Whereas, however, the Defendants seek to demonstrate that there is a sufficient difference between the apparatus seized and that of Marconi, owing to the fact that in the apparatus of the latter the transformer is composed of two entirely distinct coils, whilst the transformer of the seized appliance is formed of one single coil, one portion of which contains the primary circuit in which the current passes; that this single self induction coil also contains the transformed current of the secondary circuit in the shape of radiation current; that thus the action of the primary circuit upon the secondary circuit is alleged to take place not by induction as in the case of Marconi, but by derivation, which is expressed by stating that the apparatus seized is not a transformer like Marconi's, but an auto-transformer, which would suffice to cause the complaint of infringement to fail to the ground.

Whereas these subtleties appear to be irrelevant inasmuch as in the first place the Marconi claims do not define the transformer he proposes to use, but in his improvement patent are made applicable to all systems of transformers, so that he can equally well make use of the Tesla device adopted by him and the Oudin device, which would distinguish the seized apparatus.

Whereas further the contradiction which it is sought to establish between the transformer and the auto-transformer is scarcely more than a dispute about words; whereas, indeed, the term "transformer" was at the outset made use of to designate the apparatus serving to raise or diminish the voltage of an electric current, for instance,

by converting a current of 30 amperes at 100 volts into a current of 10 amperes at 300 volts or *vice versa;* and whereas the apparatus principally used at the outset had two separate windings and the ratio in which the voltage was raised or lowered depended upon the number of windings of the secondary as compared with the number of windings of the primary;

Whereas this apparatus was employed for other purposes than that of modifying the voltage and particularly for the transformation of electric energy into the energy of the magnetic field, the latter in turn becoming transformed into electric energy in another circuit, *i.e.*, in the secondary as an induced current;

Whereas the same effect could be obtained subsequently by an apparatus having one single winding, one portion of which only is common to the two circuits, and the whole or a part of which was placed in one only of the two circuits; whereas the ratio of change in the voltage depended upon that existing between the number of windings of the primary and the number of windings of the secondary;

Whereas this apparatus, which was first called a transformer, received the name of auto-transformer in order to distinguish it from the transformer proper, having two separate windings;

[fol. 2316] Whereas the supporters of a marked difference between the two systems allege that the auto transformer does not act as does the transformer entirely by mutual induction, but partially by mutual induction and partially by what is called inductive derivation; so that they can entirely eliminate mutual induction in order to obtain inductive derivation only, which would constitute a genuine invention;

Whereas there must be pointed out what is of great importance to the discussion, that if in an auto-transformer the whole of the winding is common to the two circuits there is no modification of voltage and consequently no effect by way of transformation of voltage, but the only function of the apparatus is by way of inductive derivation;

Whereas prior to Tesla's experiments upon high-frequency currents and very high potentials, the transformers and auto-transformers were provided with the traditional iron core, offering a more ready passage to the lines of force of the magnetic field; but whereas Tesla in order still

further to increase the voltage made use of transformers without core, which were definitely adopted in his patents of 1898 and 1899 and were, doubtless, also contemplated in the more general description of the 1900 specification;

Whereas the Oudin transformer appears to have been the only apparatus without a core employed prior to Marconi;

Whereas Commander Ferrier, on page 223 of the book already referred to, under the title, "Oudin and Tesla Transformers," examines the two appliances under discussion and which thus appear as possessing very great analogies;

Whereas under such circumstances, it can readily be understood that the learned Me. Taillefer should express himself thus:

I take it that the Oudin resonator is a transformer; it is a further transformer. * * * the adjustment of the aerial is effected by the employment of the Oudin transformer. * * * and this is interesting, for in the device impeached by Marconi we discover precisely the aerial and the employment of the resonator. Oudin uses it with the same object and for the same purpose.

For what purpose, then, is my opponent's lengthy dissertation to demonstrate that the Oudin resonator and the Marconi transformer are the same thing? I am in agreement with him * * * Marconi, in 1900, copied Lodge, Braun and Tesla; he further borrowed from Oudin that which was his characteristic feature * * * in 1898 the transmitter (Marconi) is provided with an Oudin adjustable resonator.

Whereas it is evident from all the foregoing that the substitution of an Oudin for the Tesla in the seized apparatus does not constitute any palliation for those who are charged [fol. 2317] with infringement, as Marconi, as a matter of fact employed the Oudin transformer or auto-transformer prior to 1900 and on the strength of his claims can still do so, seeing that the practical result is the same;

Whereas the excuse of incomplete syntonization in the apparatus seized as compared with the four Marconi circuits also falls to the ground in presence of the foregoing findings of fact; whereas scientific theories, however ingenious they may be, which attempt to make out that Marconi's formula of mathematical syntonization is inappli-

cable, as well as the impossibility of the seized apparatus providing the syntonization of four circuits, also fail in in view of the results of the Marconi invention, the identical working of the seized apparatus, which would not be the case without syntonization, which is the fundamental basis of a practical receiver for Hertzian waves;

Whereas it matters little whether such syntonization be the result of a mathematical formula or of the employment of adjustment by a tentative method, as Nature almost always takes an ironical pleasure in defeating absolute classification as well as any attempt to imprison it within infallible dogmatic formulæ; whereas the supporters of such formulæ, who try to set up Oudin in opposition to Tesla, derivation to induction, and the couplings of the seized apparatus to those of Marconi are entirely routed by Commander Ferrier, to whom the involved Companies appeal, and who, in his learned developments of Chapter VIII. of the work already referred to, absolutely assimilates the indirect processes of excitation, induction or derivation in respect of both the receiver and the transmitter;

Whereas the simplest method in this grave discussion is to quote verbatim concise extracts which will provide an irrefutable argument upon the point in dispute:

Indirect excitation by derivation. . . . This excitation is identical with the equation we have laid down for coupling by induction . . . in both cases the co-efficients representing the ratio of the self-induction of the coupled portion to the total self-induction of the aerial.

We can therefore apply to excitation by derivation all the conclusions which have been laid down for coupling by induction . . . the circuits are in resonance. . . .

To sum up, the following adjustments will have to be carried out:

In the case of the transmitter the two coupled circuits must be brought into resonance and the same thing applies to the two receiving circuits. . . .

It is by tentative methods that these various adjustments are effected. . . . In the case of the receiver preference is given to operating by induction, as the adjustments are far more precise when the circuits are entirely separated [fol. 2318] Whereas in any event, whether the seized apparatus formed a part or a working detail different from

the whole appliance constituting the 1900 Marconi patent, infringement would none the less exist on account of this fundamental law in respect of patents, viz., that any one borrowing the principle of a patented invention cannot evade the consequences of his infringement by introducing unimportant modifications into the invention; and whereas when the invention, as in Marconi's case, covers a combination of parts or a process producing new and useful results, any one producing the same results by making use of the main parts of the combination of the process infringes the invention, even if he has modified the combination of the process by omitting some unimportant part and substituting another equivalent part;

Whereas in the case of the seized appliances, in order to evade the complaints brought against them, it cannot be alleged that they had invented a new process as regards Marconi's process; whereas, as a matter of fact, the latter has not yet been surpassed, as Commander Ferrier acknowledges, not in his statement brought into the discussion in so unexpected a fashion that Me. Taillefer did not think fit to rely upon him, but rather upon the formal declaration to be found on page 403 of his work already referred to and which reads as follows:

It was in 1896 that Mr. Marconi accomplished the first communication by means of Hertzian waves; since that time he has continued to improve his earlier devices, and it may be said that he is still at the present moment, among all the scientists dealing with wireless telegraphy, the one who has caused the greatest advances to be made.

In 1899 the establishment of radiotelegraphic communication was the first real practical application of wireless telegraphy.

The first experiments of syntonized apparatus were made by Mr. Marconi between France and Corsica.

Whereas to sum up, so long as those who profess to obtain the same practical result as Marconi have not discovered fresh processes, but restrict themselves to introducing insignificant variations in his apparatus, they will not be able to escape from the reproach of infringement;

Whereas it is surprising to read immediately afterwards a special notice stating precisely that his system cannot be regarded as an infringement of the Marconi patent; whereas one is still more surprised to observe that the Com-

pagnie Radioélectrique, in view of their contradictory attitude, have not thought of proving that the apparatus seized against them were not their property.

[fol. 2319] Part Sixth: Summing Up. Judgment

Whereas, to sum up, this lengthy examination of the facts and of the arguments of the parties, of the documents which are for the most part very largely quoted from in order to avoid any unintentional colouring of their wording or their intention, has made apparent the unquestionably novel character of the 1900 Marconi patent; whereas doubtless the latter has drawn from the common fund of knowledge the various elements of his invention, which has no pretence to be anything else but the application of known means for the achievement of a new industrial result;

Whereas, however, in spite of the high status of the scientists whose partial discoveries it has been sought to put forward as anticipations fatal to the Marconi patent, the latter is none the less the one who first occupied and maintained an important position not only in the practical utilisation, but also has already been seen in the search for constant improvements;

Whereas, doubtless, the powerful combining process which enabled Marconi to bring the result of all previous scientific and practical research to such a high level is the most valuable testimony rendered to the genius of his predecessors, but does not in any way detract from the operations carried on by him which brought into the domain of the most remarkable industrial application all the efforts which had remained at a standstill on the purely scientific territory of theoretic ideals or on the less attractive ground of incompletely successful inventions;

Whereas in view of the tremendously rapid march of science, which is constantly placing within the reach of all, as a conquest, which quickly becomes commonplace; that which perhaps not long before appeared to be the boldest of vain imaginings, it cannot be doubted that within a short time wireless telegraphy, according to Marconi's patent, will seem but a modest preface to fresh conquests, but whereas this development, the fruit of further efforts, which will perhaps give to the conquerors of new forces, as compared to Marconi himself, the privileged position which he has inherited from his predecessors, does not

detract at all from the glory of the past, which is the common patrimony of all labourers who are early in the field.

Whereas in view of these natural laws which exert a sovereign domination over the mysterious destinies of humanity, it will be safe to relegate to a negligible background the passions which the Hertzian waves appear to have unchained and which will not even be taken into account by those who by their strict duty have only Right and Justice to consider, assisted by a modest but conscientious examination of the opposing submissions and the documents put in evidence;

Whereas these documents have enabled us to reject both the accusation of plagiarism, and the claim of forfeiture [fol. 2620] for failure to work within the legal time limit, which were brought against the patent set up and have further enabled us to investigate clearly the remarkable nature of the apparatus seized at Marseilles and Havre against the Société Radiotélégraphique and the Société Radioélectrique, both of whom are well qualified to look ahead instead of wasting time in rearguard actions, and thus to substitute for proceedings which have given rise to complaint, but which are excusable on account of the subtlety of the problems raised, the fruitful victories which doubtless await them upon new paths and in regions that were unsuspected yesterday, but which are now beginning to deliver up their mysteries;

Whereas, however, the documents put in during the arguments by the Marconi Company do not supply any means whereby the damage for which they claim compensation can be ascertained; whereas the small value of the seizures made by them show how insignificant had been up to then the actions of the Defendants; whereas under these circumstances and specially with regard to the position of the pleading, the Court is compelled to order that this damage shall be ascertained by reference, recommending the referee [illegible] to such a manner as to avoid everything that may appear like a roving commission over the affairs of the two Companies rivals of the Plaintiff Company, younger than the latter, but, perhaps, as deserving as the Plaintiffs and as desirous to serve the interests of science and the good of the public; whereas the referee must also bear in mind the theories which are put forward on both sides and which the high authority of the Counsel for parties has been able,

by considerable effort, to set forth clearly, and which makes the action of the Defendants very excusable:

For these reasons the Court—

In due form, having regard to the connection in the subject matter, consolidates the actions in order to comprise the whole under the same judgment:

Gives to Legru a record that he leaves the matter in the hands of the Court to decide as to the question of infringement:

As to the Substance:

Gives to the Société Générale de Transports Maritimes à Vapeur a record that they reserve their right to claim upon the Compagnie Générale Radiotélégraphique in the event of their working being interfered with by the substitution of the confiscated apparatus:

Holds that the Marconi Wireless Telegraphy Company are properly entitled to the patent granted on the 3rd November, 1900, with regard to improvements in wireless telegraphy; that the same is valid, as it produces an industrial result which is now beyond question:

Holds that the patent has been worked in France within the legal limit both by manufacturing the appliances and by installing them in a series of wireless telegraphy stations:

[fol. 2321] Holds that the electrical installations and apparatus seized at Marseilles from the Société Générale Maritime and the Compagnie Générale Radiotélégraphique, then at Havre from Legru and la Société Française Radioélectrique are infringements of the Marconi patent:

Restrains the Compagnie Général Radiotélégraphique and the Société Française Radioélétrique from constructing, exhibiting, installing and offering for sale appliances which constitute an infringement of the said patent:

Orders the confiscation of the apparatus seized both as regards the two Companies and the Société Générale Maritime de Transports à Vapeur and Legru:

Jointly and severally awards against the Compagnie Générale Radiotélégraphique and the Société Générale Maritime de Transports à Vapeur on the one hand and the Société Française Radioélectrique on the other, an amount of damages to be fixed by a Referee and which will comprise in addition to the claim in respect of acts committed previous to the commencement of the action, all acts of infringement committed since that time:

Appoints, in order to carry out this order, Arnitz as Referee, duly sworn, unless he should be excused from doing so by the parties;

Orders the insertion by extracts of the present Judgment in five papers published in Paris and ten published in the provinces, at the choice of the Plaintiffs, provided that the cost of each insertion shall not exceed 500 francs for the first named and 200 francs for the latter;

Orders the Defendants in the Lower Court jointly and severally to pay the costs in that action and the Defendants in the Higher Court to pay the costs in same, all which costs are to be paid to Me. Haquin in legal tender.

Orders the Société Radiotélégraphique to guarantee and indemnify the Société Générale de Transports Maritimes à Vapeur in respect of the above Judgment given against them in favour of Marconi's Wireless Telegraph Company, Limited, and at their expense to instal fresh apparatus fulfilling the conditions laid down at the time the seized apparatus were fitted up;

Orders the Société Française Radioélétrique to reimburse to Legru the cost of the confiscated apparatus in respect of their value, including expenses of installation, to be settled by Arnitz, designated and appointed as above, and who, as far as required, for this further reference will be Sworn unless the oath is dispensed with by the parties.

Orders the Société Générale Radiotélégraphique to pay the cost of the special claim of Legru, with allowance of costs to Me. Brunet, Solicitor, in legal tender.

States that as far as requisite the legal expenses, double fees and fines which may result from the present Judgment shall be included in the costs to which they reasonably belong, and this, if need be, by way of damages. M. DAYRAS, [fol. 2322] substitute Mes. SELIGMANN, TRAVERS, TAILLEFER and SARRAUTE, Advocates.

NOTE. I. II. As to the two first points, the Judgment recorded applies a principle that is constantly maintained in doctrine and juri-prudence to a particularly interesting invention, viz., that there is a patentable invention in the new combination of known means or elements resulting in a new industrial result or presenting new advantages. *Vide* especially Cass. 4 May, 1901 (Gaz. Pal. 1902. 2315); 23rd June, 1905 (Gas. Pal. 1905. 2141); and the notes, and among more recent decisions which have also applied this principle: Trib. civ. Seine 27th June, 1911 (Gaz. Pal. 1911. 2.50);

12th July, 1911 (Gaz. Pal. 1911. 2.79); with the notes and references to decided cases and authors. *Vide* likewise the cases quoted in Gas. Pal. 1912. 1, Table, reverse side, letters patent No. 15. Adde Pouillet, Taillefer and Claro; Letters patent No. 46.

III. On the third point: Usurpation of the essential idea of a patented process constitutes infringement, in spite of differences in detail; Cass, 16th January, 1912. 2. Degrees. (Gas. Pal. 1912. 1.413); Paris, 11th May, 1904 (Gas. Pal. 1904. 1. 762); 6th March, 1899 (D. 1904. 2. 317); Trib. Civ. Seine, 26th March, 1912 (Law of 4th April, 1912—Gaz. Pal. 1912. 1, reverse side, letters patent No. 31); Trib. Civ. Lyons, 9th February, 1912 (Law of 24th January, 1912 Gaz. Pal. *loc et verb. cit.*, No. 28).

General Account of Advances

This Contract. ... the twentieth ... of Septe ber ... 11 ... The Telefunken Wireless Telegraph Company of the United States

... 111 Broadway, New York,

... New York ... party of the first part and the United States ... Department ... Navy Department ... New York, N. Y., party of the second part. Witnesseth, That ... the party of the first part, ... itself ... its ... personal and legal representa... with ... of the parts of the second part as follows, viz: ... it ... the party of the second part will furnish and deliver at ... its own ... Navy Yards hereinafter specified ... the ... wants ... specified ... from the date of this contract ... respectively.

Requisition No. 82. Bureau. Naval Supply Account

Item No.

(1) 1 2-K.W. wireless telegraph set, complete, variometer type, motor generator to be wound for 125 volts, D.C. $345

(2) 1 1-K.W.wireless telegraph set, complete, commercial type, motor generator to be wound for 125 volts

(3) 1 K.W.wireless telegraph set, complete, commercial type, motor generator to be wound for ... volts D.C.

---DELIVERY---

Items 1 and 3 To be DELIVERED to Gen'l.Storekeeper Navy Yard, Brklyn, N.Y.

Item 2 To be DELIVERED to Gen'l. Storekeeper, Navy Yard, Portsmouth, N.H.

EACH WIRELESS TELEGRAPH SET TO CONSIST OF THE PARTS NAMED IN THE LIST BELOW GIVEN:

ITEM NO. 1.

This set will consist of the following:

Complete transmitter (Primary and Secondary Variometers, Spark Gap and Paper Condenser in Teak Case), New Horisontal or C.E.F. type Receiver with two Detectors and Three Telephones, Key, Transformer, Aerial Hot Wire Ammeter, Aerial Switch, Switchboard, Hand Starter, Motor Generator (with spares required by 1678), and high frequency Protecting Board.

DELIVERY:----------FIFTEEN DAYS (15), EXCEPT RECEIVER, WHICH IS TO BE DELIVERED WITHIN NINETY (90) DAYS.

ITEM NO. 2.

This set will consist of the following:

Transmitter (Spark Gap, Condenser, Transmitting Spiral and Aerial Hot Wire Ammeter), new special horisontal type Receiver with two Detectors and one Telephone, Key, Transformer, Aerial Switch, Switchboard, Hand Starter, Motor Generator with five spare sets of Brushes for Motor and High frequency Protector Board.

DELIVERY: ---------- FIFTEEN (15) DAYS, EXCEPT RECEIVER, WHICH IS TO BE DELIVERED WITHIN NINETY DAYS.

ITEM NO. 3.

This set will consist of the following:

Transmitter (Spark Gap, Condenser, Transmitting Spiral and Aerial Hot Wire Ammeter), new special horisontal type Receiver with two Detectors and one Telephone, Key, Transformer, Aerial Switch, Switchboard, Hand Starter, Motor Generator with five spare sets of brushes for Motor and High frequency Protector Board.

DELIVERY: ------ FIFTEEN (15) DAYS, EXCEPT RECEIVER, WHICH IS TO BE DELIVERED WITHIN NINETY (90) DAYS.

One complete set of spare Leyden Jars to be furnished for each of the sets under Items 2 and 3.

The switchboards should have the following:

1 A. C. Voltmeter,
1 A. C. Ammeter,
1 Frequency Meter,
1 Solenoid Switch,
2 Knife Switches,
2 Rheostats,
Fuses,
Wire.

The switchboard equipment for these sets to include the following:

1 A. C. Voltmeter,
1 A. C. Ammeter,
1 Frequency Meter,
1 Solenoid Switch,
1 Starting Switch,
2 Knife Switches,
2 Rheostats,
Fuses,
Wire.

If the sets are furnished with hand starters, no starting switch is required.

Copper coated jars to be furnished under Item No. 3.

All RECEIVERS under this contract TO BE DELIVERED at the Navy Yard, Brooklyn, N. Y., and HOME at the Navy Yard, Portsmouth, N. H.

10 - 9

1. It is hereby mutually and expressly covenanted and agreed by and between the parties hereto that the articles to be furnished or services to be performed under this contract shall conform in all respects to the requirements of the specifications hereunto annexed, which specifications, the "Instructions, Descriptions, and Conditions" printed on the reverse of the said party of the first part, shall be deemed and taken as forming a part of this contract with like operation and effect as if the same were herein recited herein; and, in any case where the specifications do not explicitly provide to the contrary, all workmanship and materials entering into the manufacture or construction of any article or articles under this contract shall be of the very best kind for the purpose and manufacture; and said article, articles, or services shall upon delivery or completion, be subject to inspection and examination by the officer or officers authorized by the said party of the second part to inspect and examine the same, and no article or service performed under this contract shall be accepted until it or they shall have been inspected and approved by such officer or officers; and any article or service not so approved shall be removed by the said party of the first part at its own expense and at its own days after notification.

2. It is further covenanted and agreed, as aforesaid, that time is an essential element of this contract and that in case the said party of the first part shall fail to make delivery of any or all of the articles or materials or to perform any or all of the services contracted for, in conformity with the conditions and requirements of the contract, and within the time or times prescribed, the said party of the second part will be damaged thereby, and the amount of said damages is hereby fixed and agreed upon and shall be deducted from the contract price, the deductions, however, not to exceed in any case 10 per cent of the stipulated value of the articles or materials not delivered, or of the services not so performed. Rejection of deliveries or performance not to be considered as waiving deliveries or performance on any days shall not have been caused by act of the Government, by strikes, riots, fire, or other disorder, delays in transportation on the part of transportation companies, or by other circumstances beyond the control of the contractor, but such circumstances shall not be deemed sufficient delays on the part of subcontractors in furnishing materials when such delays were known to the contractor at the time of the execution of this contract, unless the same be specified herein specifically as excusable delays. That the question whether delays are due to causes herein specified shall be determined by the said party of the second part.

3. It is further covenanted and agreed that if the said party of the first part shall fail in any respect to perform this contract the same may, at the option of the United States, be declared null and void, without prejudice to the right of the United States to recover for damages thereto or violations thereof, or the said party of the second part may purchase or procure in such manner and from such person or persons as he may deem proper, paying such price therefor as may be necessary in order to procure the same, such articles or materials of the kind specified herein as practicable, or procure the performance of such services as the said party of the first part shall fail to deliver or perform as required, and may demand and recover from the said party of the first part the difference between the price so paid therefor and the price stipulated in the contract, and the amount of such difference shall be paid to the said party of the first part to the said party of the second part on demand.

5. It is further covenanted and agreed that the said party of the first part shall indemnify the United States and all persons acting under them, for all liability on account of any patent rights granted by the United States that may in any way affect the sale or use of the articles herein contracted for.

6. It is further covenanted and agreed that in carrying out the provisions of the contract no convict shall be employed while undergoing sentence of imprisonment at hard labor which has been imposed by a court of the United States, any State, Territory or municipality having criminal jurisdiction, that the contract is upon the express condition that no Member of or Delegate to Congress, nor any person belonging to or employed in the naval service of, or shall be admitted to any share or part thereof, or to any benefit to arise therefrom except as a member of a corporation, and that any transfer of the contract or any interest therein to any person or party by the said party of the first part shall annul the same, so far as the United States are concerned.

AND THIS CONTRACT FURTHER WITNESSETH, That the United States party of the second part in consideration of the faithful performance of the foregoing stipulations, do hereby covenant and agree to and with the said party of the first part as follows:

That upon the presentation of the customary bills and the proper vouchers (the latter subject to inspection and examination of the said articles, articles, or services, and within ten days after such evidence shall have been obtained from the Chief of the Bureau of Navigation, Navy Department, there shall be paid to the said party of the first part at the Navy Pay Office, New York, N. Y.,

The Telefunken Wireless Telegraph Company of the United States

or to its order by the Navy Pay Officer at Navy Pay Office, New York, N. Y.,

the sum of Ninety Three Hundred Twenty Dollars -------- ($9320.00) -------

for all the articles delivered or services performed under this contract. Provided, That no payment shall be made for any of the articles or services until the same shall have been inspected and accepted by the officer or officers authorized to inspect the same.

IN WITNESS WHEREOF the said parties hereto have hereunto set their hands and seals the day and year first above written.

SIGNED AND SEALED IN THE PRESENCE OF—

U. S. Navy Pay Office, New York, N. Y.

THE TELEFUNKEN WIRELESS TELEGRAPH COMPANY OF THE UNITED STATES

August 22nd, 1912.

The Sets covered by our bid are NOT in accordance with Specification 1676, Except Paragraph 108-113-114-115 and 116 and we are unable to comply strictly with the other paragraphs of Specification 1676 without seriously impairing not only the usefulness, but also the efficiency of the set as a whole.

All spare parts as required under Paragraphs 14a, 16e(12), 26b, 32k, 37d, 55e, 66j, 70b, 100a, and 117 are included except spare parts for the generators under Paragraph 100a, because the machine we use is an Inductor Alternator with stationary Field and armature windings. As no battery is required with our Detectors, no spare primary batteries as for Paragraph 30 are supplied.

The Sets we propose supplying are of our Standard 500 Cycle Quenched Spark System and of latest Switchboard type in which the Spark Gap, Transmitting Spiral and Relay Key and the Aerial Coils, Aerial Variometer, Aerial Hot Wire Ammeter, Aerial Capacity and connections are mounted on Metal frames similiar to switchboard panels and are intended to be set up in a similiar manner, i.e., simply attached to the wall and floor. They are NOT of the Variometer Type but have a range of from 300 to 2000 meters and can be rapidly set for any of five (5) steps within this range as, for instance, 600, 900, 1200, 1600, or 2000 meters.

The transmitting condensers are made up of Standard 10 Glass Plate Leyden Jars in an aluminum porcelain insulated

August 22nd, 1912.

rack. The Leyden Jars we propose supplying will be of our usual high quality and in accordance with Paragraph 16 except e2-e3-e4-and e10 which requirements we consider entirely unnecessary if not impracticable and tending in no way to effect the operation on the durability of the sets.

The Switchboards we propose supplying will be of the simplified type as shown in our attached blueprint No. 200 same as supplied by us on all recent orders.

The Receivers we propose supplying with each set will be as follows:-

(a) Our Standard Upright Type E5 Receiver with a range up to 10000 meters and with interchangeable variable primary and interchangeable variable secondary coils and variable primary and variable secondary condensers with the primary capacity so arranged that it can be connected up with the antenna either in series or parallel by means of a switch.

(b) Same as under (a) but with a range of from 300 to 3000 meters.

(c) Our Standard Horizontal Type E4 Receiver with a range of from 300 to 3000 meters and with a variable primary and variable secondary coil and a variable primary condenser arranged so that it can be connected either in series or parallel with the antenna by means of a switch.

The Detectors we propose supplying will be of our latest form of Iron Pyrites Detectors covered by U.S. Patent dated Sept. 12th, 1911 [illegible] will be mounted on separate stands.

The [illegible] we propose supplying are of our [illegible] Station Type as shown in attached photograph No. 474 with a range of from about 275 to 3000 meters. [illegible]

[illegible] set will consist of [illegible]

August 22nd, 1912.

of apparatus:-

One Motor-Generator.
One Automatic Starter.
One Switchboard with:

- One Frequency Meter (Weston).
- One A.C. Ammeter "
- One A.C. Voltmeter "
- One Lampbracket.
- Two Fused D.P. Knife Switches.
- Two Rheostats.
- One Solenoid.
- One Set Terminals
- Instrument Fuses.

One Transformer.
One Primary Choke Coil.
One Key with Platinum Contacts.
One Transmitter with Iron Frame, including:

- Spark-gap with cover and ventilator.
- Transmitting Spiral with plugs and cords.
- Relay Key.

One Leyden Jar Transmitting Capacity in an aluminum porcelain insulated case.
One Set Aerial Coils and Aerial Variometer in iron frame with connections, aerial capacity and Aerial Hot Wire Ammeter.
One Lightning Switch.
One set of Protective appliances as per Paragraph 117.
Three Receivers as described above.
Three Detector Stands each for and including two Detectors.
Three Double Head Telephones.
One Tone Controller or Tone Tester with detector and cord.
One EKI Wavemeter as described above with

- Variable Tone Buzzer.
- One Lamp.
- One Helium Tube.

One Set of Spares consisting of -

- One Motor Armature.
- One " Field Coil.
- One Set Brushholders.
- One " Brushholder Rings.
- Ten Sets Brushes.
- Ten Set of all fuses in Switchboard.
- One set spider arms.

or -4

TELEFUNKEN WIRELESS TELEGRAPH COMPANY OF THE UNITED STATES

August 22nd, 1912.

Two Double Head Telephones.
Fifteen Telephone Cords.
Six Extra Cups with Crystals for Detectors.
Four Spare Condensers for Protectors.
Forty Spare Fuses for "
Three Helium Tubes for Wavemeter.

NEW YORK.

Telefunken Co.

Please return this proposal in duplicate, duly signed, by the above name, AUG 10 1912, with prices entered opposite each item named below, for delivery, free of charges, as specified below, within ____ days from receipt of order subject to the conditions printed on the back of this form.

Respectfully,

Navy Pay Office, U.S. Navy.

WM. JACKSON ARNOLD,

Purchasing Pay Inspector, U.S.N.

Bids to be considered must show unit prices, extensions, and total amount of bid.

ARTICLES REQUIRED.	Price of Items. Dollars	Price of Items. Cents	Per	Price Amount of Bid. Dollars	Price Amount of Bid. Cents
Requisition No. 89 Sm. Naval Supply Account. Item No. (1) Two (2) 2 K.W. 500 cycle, motor generator, reversed gap, radio telegraph sets; complete with spare parts?			Sets.	$N.S	00

To be in accordance with specifications 16-7-8, issued by Navy Dept., except as modified hereby. Bids to be made strictly in accordance with paragraph 118, specification 8, 16-7-8, and paragraph 118 (c) will be strictly observed.

Bids as per paragraph 118 d are subject to approval in each case, and, unless approved, will be required to meet the correspondence of specifications, 16-7-8, when the apparatus is presented for final acceptance.

All bidders must strictly comply with the following paragraphs of the specifications, 16-7-8, which are not to be made subject to modification by the bidders:-

Paragraph 108-Drawings, etc.
113-Tests after delivery.
114-Patents.
117-Interchangeability.
118-Omissions and misdirections.

Spare parts

118 aa-For ventilation of spark gap.
118 B if For condensers of transmitter.
118 h For electrodes of detector.
118 i-For primary batteries.
118 k-For telephone cords.
118 l-li For wave meter helium tubes.
118 e For circuit breaker contacts.
118 j For panel fuses.
118 h- do
118 c-a For motor and dynamo.
118 f For protection appliances.

Special consideration will be given bids offering apparatus in which the transmitting wave length can be continuously and readily changed, as per paragraph 6e of the specifications, over a range from 600 to 1000 meters; also for compact apparatus in accordance with paragraph 6m of the specifications.

The spitting condensers made up of Standard Leyden Jars will be required.

Three (3) receivers to be furnished with each set, as follows:

(a) One highly selective receiver of special design for receiving wave lengths up to 10,000 meters, to be furnished with a variable condenser in primary circuit with leads which can be operated by switches to put this condenser in series or in parallel with inductance or to cut it out.

(b) One highly selective receiver with variable condenser, for primary circuit as required for (a), for receiving waves from 300 to 3,000 meters for ship communication.

(c) One simplified receiver, range 300 to 3,000 meters, to consist of variable primary inductance, variable secondary, with means for varying the mutual inductance between the two circuits, and variable series condenser.

All detectors must be fitted with binding posts for detector mounted as a separate item. Detectors [illegible] mounted as described will be accepted.

Bidders will describe particularly receivers and detectors they propose to furnish.

One (1) wave meter will be required with each set.

DELIVERY at the Navy Yard, New York, for inspection and test within the shortest possible time after [illegible] a contract is signed and approved.

TO BE ADDRESSED to the General Storekeeper, Navy Yard, N. Y.

Signal Corps, United States Army.

Plaintiff's Exhibit
1 8 1 23

These Articles of Agreement entered into this twenty-seventh day of June, 1918, between C. DeF. Chandler, Captain, Signal Corps, United States Army, of the first part, and Foote, Pierson & Company, a partnership composed of George L. Foote and Henry O. Pierson, with an office at 100 Duane Street, New York, State of New York, of the second part, Witnesseth, that in conformity with copy of the advertisement, specifications, and [illegible] attached and which, in so far as they relate to this contract, form a part of it, the [illegible] C. DeF. Chandler, Captain, Signal Corps, United States Army, for and in behalf of the United States of America, and the said FOOTE, PIERSON & COMPANY hereinafter designated as the contractor, do covenant and agree, to and with each other, as follows, viz:

ART. I. That the said contractor shall manufacture for and deliver to the United States of America, the following:

EIGHT (8) Field wireless pack sets, complete with storage batteries, in accordance with Signal Corps specification No. 410, part "B," Revised, and sample set furnished the contractor. (Sets to be serially numbered in accordance with instructions contained in the order.)

ORDER No. 6808, copy attached hereto, forms a part of this agreement.

ART. II. That the deliveries of the supplies and material herein contracted for shall be made in the manner, numbers or quantities, and for each number or quantity, on or before the date specified therefor as follows, viz:

Delivery

That complete/shall be made on or before OCTOBER 25, 1918.

ART. III. All supplies and materials furnished and work done under this contract shall, before being accepted, be subject to such inspection as may be appointed on the part of the Government,

A-2

and such as do not conform to the specifications set forth in this contract shall be rejected. The decision of the Chief Signal Officer, United States Army, as to quality and quantity shall be final.

ART. IV. That for and in consideration of the faithful performance of the stipulations of this contract, the contractor shall be paid at the office of ——the Chief Signal Officer—— ——of the Army——, at ——Washington, D.C.—— for all supplies and materials delivered in conformity with the requirements of this contract, on or before the dates above specified (Article II, *supra*) *and accepted*, the following prices, viz:

EIGHT (8) wireless pack sets, at three hundred and seventy-four ($374) dollars each, making a total consideration of two thousand nine hundred and ninety-two ($2,992) dollars.

to be paid as soon as practicable after the acceptance of the same, in funds furnished by the United States for the purpose, reserving ——per cent from each payment until final settlement, on completion of the contract or otherwise.

ART. V. It is further agreed that for all supplies and materials which shall not be delivered in conformity with the requirements of this contract on or before the dates prescribed therefor in Article II, above, but which shall be subsequently delivered and accepted, the prices shall be as follows:

——none——

NOTICE - Inspectors cannot accept departures from this specification. Indicate exceptions with your bid

SIGNAL

JUN. 9 1919

SPECIFICATION, NO. 610.
(June 20, 1909).

INTRODUCTORY.

This specification covers all of the equipment necessary for the operation of the [illegible] telegraph outfit. The equipment specified herein may be [illegible] in its entirety or by unit parts in the discretion of the Chief Signal [illegible] the Army.

If the order is placed for the equipment in its entirety under this specification, the contractor will be held accountable for the efficiency and proper [illegible] of the unit parts, the inspection covering the completed outfit. The contractor will not be held accountable for the efficiency of the circuit under any condition, but will take great care to see that every detail of the specification is followed out in the construction of the apparatus covered [illegible].

This specification is intended for the information of the manufacturer only [illegible] description of the installation or operation of the equipment. This specification is divided into five parts as follows:

Part A - General Requirements.
Part [illegible] - Antennae.
Part [illegible] - Generating Set.
Part [illegible] - Train Set.
Part [illegible] - Land Generating Set.

This specification will be issued in its entirety only when bids are asked [illegible] the parts mentioned herein.

No changes [illegible] will be allowed [illegible] by the inspector [illegible]

PART A [illegible]
(P.S. No. [illegible])

1. FIELD DUTY:

These general requirements will accompany all [illegible] specification.

2. INSPECTION:

When the order under this specification is [illegible] by the Chief Signal Officer of the Army who will cause an inspection [illegible] shall be the duty of the contractor to remedy any defects pointed out by the ter and the contractor will be held accountable for any imperfections which t ter may have overlooked.

The Chief Signal Officer of the Army reserves the right to [illegible] processes of manufacture if he so desires.

All of the apparatus described in this specification, unless [illegible] may be subjected to the proper tests indicated in these requirements.

It is to be understood that this apparatus throughout must be fully [illegible] cation with absolute fidelity and any material which fails to conform to the est standard of workmanship will be rejected.

(a) TINNING: Copper wire which is insulated with rubber shall be [illegible] conform to the requirements of specification No. 403.

(b) GALVANIZING: All galvanized articles mentioned in this specification shall meet the requirements of specification No. 96.

(c) NICKELPLATING: A drop of nitric acid, specific gravity [illegible] in diameter, applied with medicine dropper to flat surface of nickelplate shall nickelplate in six minutes. In nickelplating surfaces, the nitric test will be [illegible] ticularly careful in buffing so that the nickelplate may be firmly adherent, and in case the nickelplating is rejected, the nickel plating must be buffed off and new plat put on. Any defect in the finished surface which is likely to result in flaking of the nickel after it has been in use for a short time will be considered cause for rejection of the article even though the nickel passes the other requirements of this test.

(d) COPPERING: The residue left on a fine [illegible] shall not be attacked by nitric acid having a specific gravity of 1.1.

(e) RUBBER USED FOR INSULATION: The rubber used for insulating wires [illegible] used in any part of the equipment described in this specification must conform to specification No. 430 herewith.

(f) WATERPROOFING: The compound used for saturating the braided covering for conductors in use out of doors shall be insoluble in water and shall not melt or [illegible] subjected to a temperature of 120 degrees F. nor crack at 0 degrees F. By the term "melt" is meant that it must not form any appreciable ridge of compound when placed on a piece of paper and subjected to a temperature of 120 degrees F. for thirty minutes nor must a preceptibly oily or greasy spot appear on the paper if the compound is of any oily nature.

(g) SOFT DRAWN COPPER WIRE: Soft drawn copper [illegible] shall withstand the following test:

No. 20 B. & S. or smaller — twists in six inches [illegible]
No. 12 B. & S. and not smaller than No. 18 B. & S. twists in six inches — 60.

Samples must show an elongation of 20% before breaking.

(h) Unsatisfactory workmanship will be considered cause for rejection of the equipment even though the specification may be technically complied with.

(i) Special tests will be found hereinafter.

3. MATERIALS:

(a) Hardwood: Where hardwood is specified it must be of first quality thoroughly seasoned live timber absolutely free from checks, cracks, knots, [illegible] of any description. It shall be so put together that in no case is the [illegible] ed spar for holding the apparatus together. All woodwork and interior [illegible] shall be finished to represent light mahogany as hereinafter specified.

(b) Leather: All leather parts shall be vax-tanned, best quality [illegible] sewing being extra strong and rivets being used wherever possible to [illegible] cutting of threads in typical climates. Threads used must be the strongest [illegible] able, thoroughly waxed.

(c) Commercial fittings: Where commercial [illegible]

3. GENERAL REQUIREMENTS---- (2)

(d) Brass: Sheet brass shall be what is commonly known as low brass and shall have a composition approximately as follows:

Copper ---65%
Zinc----35%

Brass for binding posts, etc. shall have approximately the following composition:

Copper----67
Zinc------33

(e) Hard rubber: The hard rubber covered by this specification shall be of the best grade obtainable made up from best Para rubber and sulphur with no other ingredients. Samples will be subjected to chemical and mechanical tests.

(f) Fibre: The fibre covered by this specification shall be red in color and so treated as to be impervious to moisture. Samples shall be subjected to test for mechanical strength and hygroscopic qualities.

(g) Slate: All slate specified herein shall be of the best grade Arnson oil finished dead black. The rear of the slate will also be thoroughly oiled.

(h) Marble: All marble shall be white Italian, free from all flaws whatsoever.

FINISH.

(a) Brass work will be in four standard finishes, as indicated hereinafter. The finishes will be designated as follows:

Standard dark finish.
Standard nickel finish.
Standard telegraph finish.
Dip lacquered.

All brass work will be finished in one of these styles.

(b) The standard dark finish for brass work not a contact surface will be obtained by the use of either of the following methods:

1. By the use of a solution of arsenic made by dissolving common white arsenic, arsenious oxide, in hydrochloric acid.

2. Copperplate the part to be finished, then using an alkaline polysulphide solution such as sodium polysulphide.

Care must be taken in the preparation of the parts to be finished to see that they are entirely free from lacquer or grease. Clear lacquer will be applied to the parts after the desired finish with the above solutions has been secured.

(c) The nickel finish will conform to the requirements of Par. 2.

(d) The standard telegraph finish will conform to that of the best grade telegraph instruments, being polished and lacquered.

(e) Brass parts not ordinarily exposed will be dip-lacquered, care being taken that all parts are thoroughly cleaned before lacquering.

(f) The standard finish for copper parts not forming part of a contact will be obtained by dipping into a solution of alkaline polysulphide, such as sodium polysulphides. Care will be taken to see that the parts to be finished are free from grease or lacquer before dipping in the solution and clear lacquer will be applied to the parts after the desired finish is obtained.

(g) The standard finish for all woodwork is as indicated below. This finish will be accurately followed for all wooden parts of this equipment.

The following applies only to specification No. 410 - Field Wireless Set, which reads:

"All woodwork and interior of pack chest shall be finished in the following manner:

Stained light mahogany and rubbed down after being dried for twelve hours. Three coats of varnish shall then be applied. The wood is shall be rubbed down after each operation with pumice stone and crude oil. The finish when complete shall be smooth but not glossy, and shall present no evidence of open pores in the wood, and shall not be easily scratched or marred."

The following applies to Specifications

Nos. 464—Standard Marine Wireless Telegraph Equipment,
479—Station Wireless Equipment, 10 K. W.
485— Wireless Telegraph Equipment, 1 K.W. Station Set,
516—Wireless Equipment "Joseph Henry,"
518—Station Wireless Telegraph Set, 5 K. W.

Woodwork shall be finished as follows:

Filled with medium grade [illegible] after being [illegible]

AT-14

hours shall be covered with a coat of orange shellac. After being rubbed smooth with sand paper, a coat of rubbing varnish shall be applied and rubbed down with pumice stone and crude oil. The woodwork shall receive two coats of rubbing varnish and shall be rubbed down after each operation. The finish when complete shall be smooth but not glossy, and shall present no evidence of open pores in the wood, and shall not be easily scratched or marred."

The successful bidder will decide upon the color and the quality of the finish from the sample which will be supplied him.

(h) Hard rubber, where exposed, will invariably be polished.

(i) Ironwork will be galvanized to meet the requirements of specification No.96

5-PROPERTY NUMBERS:

The property numbers shall be serial and shall accompany the order. If these numbers are not indicated in the order the manufacturer shall take care to put them and see that they are on the instruments before inspection.

6-METAL WORK:

All metal work shall be provided with a rustless coating of one of the types specified above and it shall meet the test indicated above.

If not otherwise specified, the metal parts, unless magnetic qualities require otherwise, shall be made of brass. All threads and screws shall be U. S. commercial standard.

7-NAME PLATES:

(a) The name plates shall be of brass and shall conform to the drawings of the several instruments.

(b) These plates will in all cases be machine-engraved.

(c) These plates will be ordered in one of two finishes as follows:

Standard dark finish,
Nickel grain finish.

(d) The standard dark finish will be obtained as indicated in Paragraph 4-b and the letters will be filled with white enamel.

(e) The nickel grain finish shall conform to Signal Corps standard and letters shall be black-finish. Sample will be furnished the manufacturer.

8-PACKING:

All articles described herein must be packed with great care. The packing will be made the subject of inspection and if crates are not satisfactory to the inspector, the materials will not be accepted until proper package is provided.

(f) The insulation between the primary and secondary windings shall withstand the application of an alternating current of 40,000 volts for 10 seconds.

The primary winding shall withstand the application of 500 volts alternating current for a period of one minute.

(g) The outside containing case shall receive two coats of hard transparent varnish with rubbed finish. The top side of the case shall have stamped in the wood, in letters not less than 1/4" high, the following words:

INDUCTION COIL
U. S. SIGNAL CORPS.

7-INTERRUPTER:

The interrupter furnished under this specification shall conform accurately to dimensions given in drawing 549 and meet the following requirements:

(a) Material: All materials used must be the best of their kind.

(b) Workmanship: Every part of the work on this interrupter must conform to the highest grade of workmanship.

(c) The base shall be hard rubber polished on all exposed surfaces.

(d) Fittings: Fittings on exposed surfaces shall be provided with gray nickel finish and other not forming a part of the magnetic circuit or not otherwise shown on the drawing, shall be of brass.

(e) Windings: The magnet shall be wound with No. 34 B. & S. gauge single cotton, covered copper magnet wire and shall be thoroughly water-proofed. Magnet heads shall be fibre and a fibre shall shall be interposed between the magnet windings and the core. Windings shall each have a resistance of about 9 ohms. The finished bobbins shall be covered with pebble cloth.

(f) Magnetic circuit: Care shall be taken to make accurate joints in all parts of the magnetic circuit. This will receive special attention at inspection.

(g) Insulation: All materials for insulation, including milled heads for fastening screws, insulation for busser contacts, and the base shall be of the best grade of hard rubber.

(h) Contacts: Contacts shall be of platinum and shall be fully equal to dimensions shown on drawing.

(i) Contact springs: Particular care must be taken in the selection of the contact springs in order that rapidity and certainty of action of the interrupter may be secured. It may be necessary to make several changes before a satisfactory spring is obtained and the contractor will be required to satisfy the inspector in this particular. The dimensions shown in drawings are furnished as a guide, the complete interrupter must equal sample in operation.

(j) Tests: Inspections will particularly include the efficiency of the springs, accuracy of the contacts, insulation of windings and contacts, accuracy of fit of the adjusting screws, general appearance of the completed interrupter as well as such other tests as the inspector may deem necessary.

8-SIGNALING KEY:

The key shall be standard open circuit log telegraph key provided with special platinum contacts as shown on drawing 560, and meeting the following requirements:

(a) Base: The base shall be of brass or other approved non-corrosive metal.

(b) Springs shall be of phosphor bronze.

(c) Levers shall be made of phosphor bronze.

(d) Trunnions shall be of blued steel or phosphor bronze.

(e) Insulation: The switch knob, lever tip, and other insulation shall be of hard rubber.

(f) All metal work shall have a standard dull finish.

(g) Marking: The letters U. S.S. C. shall be stamped on the base.

9-CONTROL SWITCH:

(a) The control switch shall conform to drawing 672 in all details.

(b) The control switch shall be made of the best Lake copper, dead-file finish, to dimensions.

(c) All hard rubber used shall conform to General Requirements, Part A, of this specification.

(d) The construction must conform in general to the requirements of specification No. 360, covering the manufacture of knife switches.

10-TUNING COIL:

The tuning coil furnished under this specification shall conform to the dimensions given for the short coil of drawing 497c and meet the following requirements:

D-17

SPEC. 610 -- Part D---(3)

(a) Cylinders:- Cylinders shall be of hard rubber per General requirements, Part A, of this specification, and shall have a spiral groove with 24 pitch to accommodate wiring.

(b) The cylinder shall be wound with No. 24 B. & S. Gauge hard brass wire. After winding on the cylinder, this wire shall be heavily copper-plated and nickeled. No hot plating shall be used in the plating process and particular care shall be taken to have the completed cylinder entirely free from plating and cleansing solutions.

(c) Contactors and adjusting bars shall be made of brass, grey nickel finish.

(d) All other metal work shall be brass, polished, and heavily dip-lacquered.

11-SILICON DETECTOR:

This shall be the standard silicon detector as made by the Wireless Specialty Co., 71 Nev Street, New York, and shall be furnished with nickel-plated mounting, retaining chain for button, and fittings complete for connection to the wireless receiving set.

12-TERMINALS:

(a) The terminals shall conform to drawing 569.

(b) The lock nut binding posts shall conform to dimensions shown on drawing 569.

(c) All hard rubber used shall conform to General Requirements, Part A, of this specification.

(d) Workmanship and finish must be first-class throughout.

13-TELLTALE LAMP:

(a) The telltale lamps shall be furnished complete with hard rubber mounting as shown on drawing 631. Two spare incandescent lamps shall be furnished with each mounting ordered under this specification.

(b) All hard rubber shall conform to General Requirements, Part A, of this specification.

(c) Binding posts shall be of brass, standard nickel finish.

14-LEYDEN TUBE CONDENSER:

This condenser shall be furnished complete with tubes and shall meet the following requirements:

(a) The Leyden tube terminals shall conform to drawing 568. One pair of terminals ordered shall comprise one set of upper terminals and one set of lower terminals as shown on the drawing.

(b) The spring clips shall be of the best grade of German silver. These shall be carefully formed to outline shown on drawing. Particular attention will be given to forming these spring clips so that the strength of the material will not be impaired in the process of forming.

(c) The base shall be made of hard rubber which shall meet the General Requirements, Part A, of this specification.

(d) The Leyden tubes shall be designed for mounting on the terminals of drawing [illegible] shall be the Tolefunken make or equal. The dimensions shall be about 12 inches by one inch in diameter. The tubes shall be provided with copper strip protection as shown in drawing 568.

(e) The electrostatic capacity of these tubes shall be about .00075 M.F.

(f) Special care shall be taken by the manufacturer in packing the tubes ordered under this specification in order that the breakage in shipment may be reduced to the minimum. 1 spare tube shall be furnished with each condenser.

15-DOUBLE HEAD RECEIVER:

This shall be the double head telephone receiver, H.W.Sullivan make, pattern A, [illegible] resistance of about 2,460 ohms. It will be furnished with a five-foot tinsel cord, silk covered. Three spare cords and six spare ear caps shall be furnished with each receiver.

16-TRUNKS:

The trunks shall be the Leatheroid Trunk Co's. standard make or equal and shall [illegible] dimensions of 21 inches long, 12 inches wide, and 12 inches deep, of which 2-1/4 inches shall be in the cover. The 21 inches by 12 inches inside surface of the cover and the bottom of the trunk shall be fitted with 3/8-inch lining of white pine [illegible] brass screws. The inside dimensions above shall obtain after these linings are in place.

The trunk shall be three-ply, made up with one thickness of poplar between two of leatheroid, the inside being lined with chase-cloth.

All corners shall be reinforced with leatheroid and corners shall have mild [illegible].

The trunk shall be furnished with a good improved type of double hinged trunk lock with duplicate keys [illegible].

The lid shall have a rubber valance [illegible] to prevent moisture from entering [illegible].

2717

AT-18

...l-inch side of the trunk.

...t there shall be secured by means of flat head
...s, 1-1/2 inches x 2-1/4 inches by 5-inches for

...It. two coats of olive drab paint made up according
...pounds of white lead ground in raw linseed oil; one pint
...drier; one quart raw linseed oil, one pound raw umber.

...storage battery meeting the following re-

...plied shall consist of two units of four cells each
...for unit and six amperes charging rate, and shall be

...-spillable, provided with vents, hard rubber screw
...over these caps.
...carrying current shall have hard rubber covering.
...have their polarity stamped on cover.
...shall be of canvas covered with rubber composition to resist

RETURN TO OFFICE
RECEIVED
JAN 19 1912
Series 1912 War. Dept.

This Articles of Agreement entered into this ------seventh------ day of December---, nineteen hundred and eleven, between -------R. J. Burt------ Captain,----------, Signal Corps, United States Army, of the first part, and the Wireless Specialty Apparatus Company, one of whose principal offices is at No. 81 New Street, New York City,---------- in the county of --------New York----------, State of-----New York-------, of the second part, WITNESSETH, that in conformity with copy of the advertisement, specifications, and proposal hereunto attached, and which, in so far as they relate to this contract, form a part of it, the said ----------R. J. Burt, Captain,---------- Signal Corps, United States Army, for and in behalf of the United States of America, and the said ----------WIRELESS SPECIALTY APPARATUS COMPANY---------- (hereinafter designated as the contractor,) do covenant and agree, to and with each other, as follows, viz:

Article I. That the said contractor shall manufacture for and deliver to the United States of America, the following:

ITEM:
1. Two (2) Sets, receiving, type 1-P-98, including telephone headsets, Wireless Specialty Apparatus Co. make.

Art. II. That the deliveries of the supplies and materials herein contracted for shall be made in [illegible] and for each number or quantity, on or before the date specified [illegible], viz:

That complete delivery shall be made on or before January 17, 1912.

[illegible] time under this contract shall, before [illegible] be a [illegible] on the part of the Government.

ART. IV. That for and in consideration of the faithful performance of the stipulations of this contract, the contractor shall be paid at the office of ----The Chief Signal Officer--------of the Army----------, at---Washington, D. C.-----, for all supplies and materials delivered in conformity with the requirements of this contract, on or before the date above specified (Article II, *supra*) and *accepted*, the following prices, viz:

ITEM:

1. Two (2) Receiving Sets, at three hundred twenty-five dollars ($325.00) each;

   Making a total consideration of six hundred and fifty dollars ($650.00).

to be paid as soon as practicable after the acceptance of the same, in funds furnished by the United States for the purpose, reserving ____ per cent from each payment until final settlement, on completion of the contract or otherwise.

ART. V. It is further agreed that for all supplies and materials which shall not be delivered in conformity with the requirements of this contract on or before the dates prescribed therefor in Article II, above, but which shall be subsequently delivered and accepted, the prices shall be as follows:

Contract No. 133
Series No. 3

Account of { No. of Station Bureau
A. B. General Account of Advances

Articles of Agreement, Made and concluded this twenty-first day of September, one thousand nine hundred and eight, by and between Frederick Security Apparatus Co. of No. 61 Pearl Street, New York, in the State of New York, party of the first part, and Rear Admiral Charles O'Neil, Chief of the Bureau of Supplies and Accounts, United States Navy, Navy Department, Washington, D.C., acting under the direction of the Secretary of the Navy, party of the second part, witnesseth, that, for and in consideration of the payments hereinafter specified, the party of the first part, for itself and its personal and legal representatives, doth hereby covenant and agree to and with the party of the second part, as follows, viz:

1. That it, the said party of the first part, will furnish and deliver, at its own risk and expense, at such place in the Navy Yard, Brooklyn, N.Y., as the Commandant thereof may direct, within the specified days from the date of this contract, the articles, and at the price set opposite each item, respectively:

Requisition No. by Sm. Naval Supply Account.
Item No.

(1) Two (2) 5 K.W. 500 cycle, motor [redacted] ator, [redacted]nched gap, radio telegraph sets, complete with spare parts, $5499.00 set

To be in accordance with specifications 16-T-5, issued by Navy Dept., except as modified hereby. Bids to be made strictly in accordance with paragraph 118, specifications, 16-T-5, and paragraph 118 (c) will be strictly enforced.

Variations as per paragraph 118 d are subject to specific approval in each case, and, unless approved, the contract will be required to meet the corresponding details of specifications, 16-T-5, when the apparatus is inspected for final acceptance.

All bidders must strictly comply with the following paragraphs of the specifications, 16-T-5, which are not to be made subject to modification by the bidders:-

Paragraph 108-Drawings, etc.
113-Tests after delivery.
114-Patents.
115-Interchangeability.
116-Omissions and misdirections.

Spare parts

14-aa-For ventilation of spark gap.
16-B-12-For condensers of transmitter.
28-b For electrodes of detector.
30-For primary batteries.
33-k-For telephone cords.
37-d-13-For wave meter helium tubes
38-e-For circuit breaker contacts.
38-j-For panel fuses.
70-b- do
100-a-For motor and dynamo.
119- For protection appliances.

Special consideration will be given bids offering apparatus in which the transmitting wave length can be continuously and rapidly changed, as per paragraph 4a of the specifications, over a range from 600 to 8000 meters; also for compact apparatus in accordance with paragraph 8a of the specifications.

Transmitting condensers made up of Standard Leyden Jars will be required.

Three (3) receivers to be furnished with each set, as follows:

(a) One highly selective receiver of special design for receiving wave lengths up to 10,000 meters, to be furnished with a variable condenser in primary circuit with leads which can be operated by switches to put this condenser in series or in parallel with inductance or to put it out.

(b) One highly selective receiver with variable condenser, for primary circuit as required for (a), for receiving waves from 300 to 3,000 meters for ship communication.

(c) One simplified receiver, range 300 to 3,000 meters, to consist of variable primary inductance, variable secondary, with means for varying the mutual inductance between the two circuits, and variable series condenser.

All detectors must be fitted with binding posts for a detector counted as a separate item. Detectors suitably mounted on receivers will be accepted.

Bidders will describe particularly receivers and detectors they propose to furnish.

One (1) wave meter will be required with each set.

DELIVERY at the Navy Yard, New York, for inspection and test within the shortest possible time, time to be a factor in award of contract.

TO BE DELIVERED to the General Storekeeper Navy Yard

12722

ref-3-4

Accepted for material in accordance with the specifications of requisition, except as modified in specifications (copy attached), blueprints, drawings, etc., submitted with bid:

Wireless Specialty Apparatus Co. proposes to furnish apparatus as per the following details:

MOTOR GENERATOR:
Motor -- Volt D.C., shunt interpole, flat speed regulation. 1875 R.P.M. Generator-- 250 volt, 500 cycle, special wave form alternator, designed specially to operate with remainder of transmitting unit. (We reserve the right to furnish our new type, (Patents pending) interpole alternator with variable wave form). Both types have very close VOLTAGE regulation and high over all efficiency. Spares: 4 sets brushes.
PROTECTIVE APPLIANCES, will be supplied.
TRANSFORMER:
Type: Open core, dry, specially designed to operate without exterior resistance with remainder of transmitting unit. Spares: 2 secondary sections.
[illegible] SPARK GAP:
New design, perfect cooling by special central draft. (We reserve right to furnish our new type Tubular gap). This latter having new feature of cooling and perfect sparking alignment with ease of dismantling).
LOW TENSION SWITCHBOARD:
Black slate, angle supports, on which will be mounted:
1. S.E.Hot wire voltmeter,
1. S.E.Hot wire ammeter,
1. S.E.Single phase wattmeter,
1. Hartman & Braun Reed type frequency indicator.
(All instruments calibrated for 500 cycles).
AUTOMATIC MOTOR STARTER:
Special contactors for distant control of A.C., line and field; besides motor control.
Generator and motor field rheostats, etc., as per photographs.
TRANSMITTING INDUCTANCES:
New type, (patents pending) transmitting inductances will be supplied giving continuously variable wave length of 600 to 2000 meters with no switches, exciting and radiating circuits, always in resonance and with maximum coupling. This type of inductance is absolutely new and gives the widest range of inductance variation of any known form of inductance.
TRANSMITTING CONDENSERS:
Standard type W.S.A.Co's. copper deposit jars in Rack. Capacity, .08 Mfd.,
or
We should prefer to furnish our new design plates in absolutely oil tight tanks and cases. This latter type occupies very much less space than the jar type of same capacity.
RADIATION METER:
Hartman & Braun hot wire type, 0-50 amperes, unshunted type.
TRANSMITTING KEY:
Magnetic relay type. A very efficient key capable of operating at a maximum speed of 60 words per minute. Hammer blow type. Signalling accomplished by means of small Morse key.
ANTENNA SWITCH:
Mounted on high tension switchboard panel.
LIGHTNING SWITCH:
As per photograph submitted.
HIGH TENSION SWITCHBOARD:
White marble, same dimensions as low tension switchboard, mounted complete with the following apparatus:
Quenched spark gap.
Wave length and coupling control handles with indicators.

(continued)

(Sheet #2 - continued)

Radiation Meter,
Change-over switch,
(Transformer, condenser and inductances mounted on back of board.)

RECEIVING APPARATUS:

Three Receivers.

(a) New Type 1915, 1-P-76, complete receiver, special design for receiving wave lengths up to 10,000 meters. Highly selective.

(b) New Type 1915, 1-P-76, complete receiver, for receiving wave lengths of 300 to 4200 meters. Highly selective.

(c) New Type 1915, 1-P-76, complete receiver, for receiving wave lengths of 300 to 4200 meters. Simplified type for stand-by conditions.

(b) and (c) will be provided with a Listening-in-key and special phones.

All these receivers are furnished with standard HERTZITE and SILICON ARSENIC detectors and are arranged for very efficient spark group frequency tuning. 3 pairs Pickard adjustable telephones furnished with each set. Telephones can be furnished if desired to be strongly responsive or selective to 1000 sparks per second. Spares as called for in requisition will be supplied.

WAVE METER:

Type P. W. M., will be supplied.

DELIVERY:

One set to be delivered within fifty-three (53) days from date of contract.

One set to be delivered within seventy-eight (78) days from date of contract.

P R I C E:

The price to be $3699.00 per set, making a total of $7398.00.

Total Cost: $1,186.00

ARTICLES REQUIRED

Requisition No. ...

FOR DELIVERY AT NAVY YARDS MARE ISLAND, CAL. AND NEW YORK, N.Y.

Rec. 186 B.&A.

Item 1. Five (5) S-A... radio sets for ship installations.

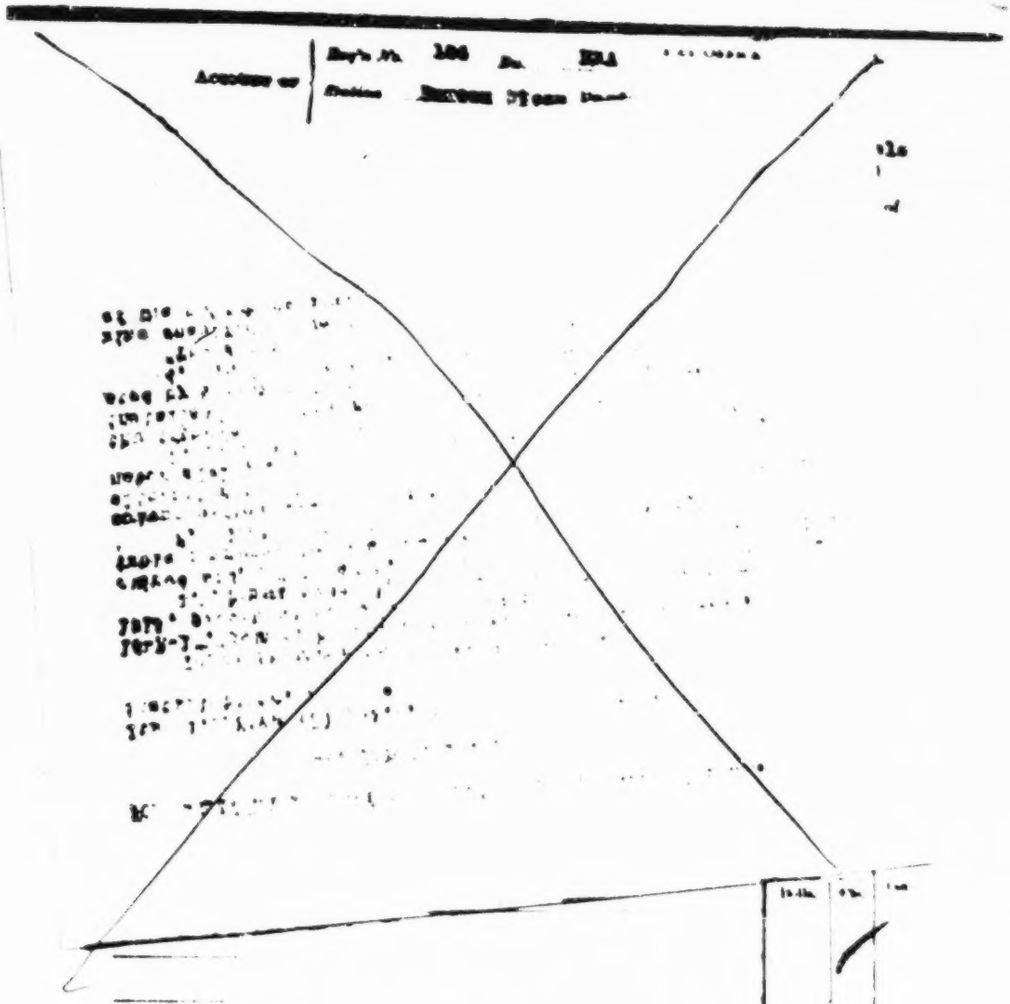
To be in accordance with "Specifications 18-R-1", issued by the Navy Department January 1, 1916, except as modified below:-

1. Panel assembly of the transmitter ... required and, if offered, the different ... table to ready removal and separate ... selector ..., one ... alternator armature circuit and the other ... motor field,

3. The automatic starting ... the transfer switch ... installation in the radio room, ... operated by a push button switch located on ...

4. In lieu of par. 14 (a)(2) substitute the following:

"The set shall ... nine specified were ... of the switch panels.



4. Under par. 24(b) add: "Contract number and requisition number."

5. In lieu of paragraphs 25(f) and 25(g), substitute the following:

"All apparatus, including transmitters and receivers, shall be capable of continuous operation at a room temperature of 50° C. and a humidity of 90% saturation. No part of the transmitting apparatus having cotton insulation shall show a final temperature greater than 90° C. and no other part of the apparatus shall show a final temperature greater than 105° C., nor shall any part of the apparatus show deterioration or faulty operation. Continuous operation shall be based on a test for a period of eight consecutive hours at full power at a sending rate of about 20 words per minute; power to be measured with key depressed."

6. Condenser for protective appliances required by par. 21 (a)(4) shall be of not less than 0.05 mfd. instead of 0.1 mfd. capacity.

8. Paragraph 21(c) of the specifications 16-R-1 required that protective appliances shall be provided for use in the following locations:

(1) Across the terminals of the low tension winding of the transformer, 2 sets, 1 for each transformer.

(2) Across the terminals of the armature of the alternator, 2 sets, 1 for each alternator.

(3) Across the terminals of the fields of the alternator, 2 sets, 1 for each alternator.

(4) Across leads to cooling motor and spark gap.

Paragraph 21(d) requires protective appliances as specified for each D.C. motor of the two motor-generators.

9805.00

Cont -1 a

9. The spare parts, including spare brushes, gaskets, contacts, fuses, quenched gap plates, spares for blower motor, etc., provided with each set, except those for the motor-generator and except the spare condenser units, shall be delivered in a suitable hardwood box with metal hinges and lock. The box shall be suitably fitted to hold the spare parts securely and each spare part shall be readily removable without disturbing the other contents of the box. The spare parts for the motor-generator shall be provided in a separate box.

10. Bidders shall state what reduction will be made from prices offered in case the government, at its option, supplies any or all of the following apparatus.

(1) Lightning switch.
(2) Antenna transfer switch.
(3) Condenser rack.
(4) Wave changing switch.
(5) Oscillation transformer.

11. The unit price for each set shall include all spare parts as required by the specifications and as offered but an itemized list of the spare parts as required by the specifications and so offered must accompany each bid and the unit price of each spare part so offered must be stated. This information is desired for future reference in placing orders for spare parts. The particular attention of bidders is invited to this paragraph, and the preceding paragraph, which must be strictly complied with. Failure to meet the requirements of these paragraphs will render the bid liable to rejection.

12. Liquidated damages for delay in delivery shall be calculated at the rate of [illegible] per day per set for each set not delivered complete at the expiration of the contract period.

Delivery to be made within 240 days from date of contract. Delivery of the first two sets to be made at the Navy Yard, New York, and of the other three sets at the Navy Yard, Mare Island, Cal.

6. It is hereby mutually and expressly covenanted and agreed by and between the parties hereto that the articles or articles to be furnished or services to be performed under this contract shall conform in all respects to the requirements of the specifications hereunto annexed, which specifications the "Instructions, Reference, and Conditions," printed on the proposal of the said party of the first part, shall be deemed and taken as forming a part of this contract with like operation and effect as if the same were incorporated herein; and, in any case where the specifications do not explicitly provide to the contrary, all workmanship and materials entering into the manufacture or construction of any article or articles under this contract shall be of the very best quality and manufacture, and said article, articles, or services shall upon delivery or completion, be subject to inspection and examination by the officer or officers authorized by the said party of the second part to inspect and examine the same; and no article furnished or service performed under this contract shall be accepted until it or they shall have been inspected and approved by said officer or officers; and if not so approved shall be removed by the said party of the first part at its own expense and within ten days after notification.

7. It is further covenanted and agreed, as aforesaid, that time is an essential element of this contract and that if the said party of the first part shall fail to make delivery of any or all of the articles or materials or to perform any work or services herein specified in accordance with the conditions and requirements of the contract, and within the time herein provided (the said party of the second part reserving the right thereby and thereupon to extend the time for delivery), then the said party of the second part may purchase in the open market and thereafter furnish and deliver such articles or materials as may be necessary to complete the amount of such articles or materials undelivered by the said party of the first part, and the said party of the first part shall make deductions on account thereof from the contract price aforesaid, or

8. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

9. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

10. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

11. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

12. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

13. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

14. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

15. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

16. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

17. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

18. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

19. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

20. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

21. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

22. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

23. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

24. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

25. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

26. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

27. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

28. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

29. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

30. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

31. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

32. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

33. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

34. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

35. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

36. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

37. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

38. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

39. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

40. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

41. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

42. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

43. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

44. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

45. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

46. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

47. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

48. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

49. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

50. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

51. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

52. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

53. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

54. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

55. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

56. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

57. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

58. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

59. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

60. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

61. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

62. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

63. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

64. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

65. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

66. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

67. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

68. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work to be performed under this contract, and the said party of the first part shall not be entitled to receive any further payment under this contract.

69. It is further covenanted and agreed that if the said party of the first part shall fail to perform the work to be performed by it under this contract within the time herein specified, or if the said party of the first part shall fail to perform any of the covenants herein contained on the part of the said party of the first part to be performed, then the said party of the second part may, by written notice to the said party of the first part, declare this contract null and void, and thereupon the said party of the second part may enter upon the premises of the said party of the first part and take possession of all articles and materials which may be upon the premises and which have been purchased or procured by the said party of the first part for the performance of this contract, and may employ any other person or persons to complete the work

of 370 Broadway, New York City

in the State of party of the first part, and the UNITED STATES, by

Paymaster of the Pay Office of the United States Navy Pay Office Washington, D.C.,

acting under the direction of the Secretary of the Navy, party of the second part, Witnesseth, That,

for the consideration hereinafter specified, the party of the first part, for

itself and its executors, administrators, successors, and its personal and legal representatives, does

hereby covenant, promise, and agree with the party of the second part, as follows, viz:

First: That the said party of the first part will furnish and deliver at its own

proper cost and expense at the Navy Yard, Washington, D.C.,

the following articles, viz: to be new and perfect in every respect, and to be delivered within 90 days from the date of this

contract, at the prices set opposite each item, respectively:

Item	1.	30 Ea.	each
"	2.	4 Ea.	"
"	3.	2 Ea.	"
"	4.	2 Ea.	"
"	5.	200 Ea.	"
"	6.	25 Ea.	"
	7.	Total	7,625. 00

Item

1. 30 single ultraudion detectors, complete with 6-volt Hudson filament, double bulb, without telephone receivers,
2. 4 ultraudion detections, complete with 12-volt Hudson filament, double bulb, and telephone receivers
3. 2 receiving cabinets, complete,
   To be specially designed for use with and to include 6 volt Ultraudion detector. Detector and receiving circuits to be in separate cabinets. Range of wave lengths of receivers to extend to 10,000 meters.
4. 2 receiving cabinets, complete. To be specially designed for use with, and to include, 12 volt ultraudion detectors. Detector and receiving circuits to be in separate cabinets. Range of wavelengths of receivers to extend to 10,000 meters.
5. 200 Hudson filament, 6 volt, double bulbs, for use with Item 1
6. 25 Hudson filament, 12 volt, double bulbs, for use with Item 2.

Each bulb supplied under Items 5 and 6 shall be enclosed in a separate container. The container shall be suitably inscribed with a description of the enclosed bulb which will indicate exactly the apparatus with which it is to be used, in order to prevent confusion with bulbs of similar appearance designed for other purposes. Preferably containers for bulbs of different classes should, be readily distinguishable through differences in shape or color of markings.

Each piece apparatus supplied under Items 1, 2, 3 and 4 shall be accompanied with full wiring diagram and detailed instructions for the care and operation of the same.

The best workmanship and material shall be employed throughout.

To be inspected at place of delivery, and subject to approval after inspection.

PATENTS AND DESIGNS ACT, 1907.

IT IS HEREBY CERTIFIED by the Comptroller-General of Patents, Designs and Trade Marks that on the 16th November, 1904, John Ambrose Fleming, of University College, Gower Street, in the County of London, Doctor of Science, made an application (with provisional specification) for a Patent for an invention the title of which is "Improvements in instruments for detecting and measuring alternating electric currents"; that the application in question was numbered 24,850 of 1904; and that a complete specification (including drawings) was left in connection therewith on the 15th August, 1905.

It is also certified that the said complete specification was accepted and placed open to public inspection on the 21st September, 1905; that a Patent was granted in respect of the said application on the 7th December, 1905, and sealed as of the 16th November, 1904; and that the annexed are true copies of the provisional specification and complete specification and drawings as accepted.

This certificate is issued for use in legal proceedings in the United States of America.

PROVISIONAL SPECIFICATION.

Improvements in Instruments for Detecting and Measuring Alternating Electric Currents.

I JOHN AMBROSE FLEMING of University College, Gower Street, in the County of London, Doctor of Science, do hereby declare the nature of this invention to be as follows:

It is well known that alternating electric currents can only be detected and measured by the use of some instrument, the indications of which do not depend upon the direction of the current. Hence an instrument of which the indication is dependent upon the heating of a wire by the current commonly known as a hot wire instrument is suitable for the above purpose. Also one depending upon the attraction or repulsion of electric current, commonly known as an electrodynamometer, because in both these cases the indication or reading of the instrument is the same even if the current direction is reversed.

On the other hand, an ordinary galvanometer of the movable needle or movable coil type cannot by itself be used for detecting or measuring alternating currents because it only gives an indication with a unidirectional current and is therefore unaffected by an alternating current.

The object of my invention is to provide a means by which an ordinary galvanometer can be used to detect and measure alternating electric currents and especially high frequency alternating currents commonly known as electric oscillations.

The means I employ for this purpose consists in the insertion in the circuit of the alternating current of an appliance which permits only the passage of electric current in one direction and constitutes therefore an electrical valve.

I construct it as follows:—

In a glass bulb, I seal two or more carbon filaments such as are used for the manufacture of electric lamps. These filaments each have their own separate terminals. One or more of these carbon filaments may be replaced by loops of platinum wire, provided at least one carbon filament is used. A high vacuum must be made in the bulb. Two such bulbs are employed and for the sake of simplicity, I may describe the mode of use when a double carbon filament in each bulb is used. The two bulbs are each associated with a small insulated primary or secondary battery of sufficient voltage to bring one of the filaments to bright incandescence of greater intrinsic brilliancy than if used as an incandescent lamp. The bulbs are connected in parallel with each other and inserted in the alternating current circuit, but so that an incandescent filament and a dark or cold filament in each bulb form the electrode or connection for the current to be measured to enter and leave the bulb.

In series with one of the bulbs is placed an ordinary galvanometer. In the two branch circuits formed of the two bulbs, one in series with a galvanometer the local insulated batteries are arranged to ignite carbon filaments at opposite ends. That is to say, the carbon filament nearest to one common terminal is the ignited filament in one bulb and that farthest from the same common terminal in the other bulb.

These bulbs have the property that inside the bulb, negative electricity can move from the hot to the cold carbon filament even under a very low electromotive force but it cannot move in the opposite direction. Hence, owing to the arrangement of the bulbs, the alternating current arriving at the common terminal splits and all the positive alternations pass through one bulb and all the negative through the other bulb. The galvanometer is therefore affected solely by currents flowing in one direction. The bulbs serve the purpose of separating out the two constituents of the alternating current.

In place of two bulbs, one only may be used in series with a galvanometer and then the bulb only allows currents to pass in one direction and the galvanometer gives an indication.

The device is especially applicable to the detection and measurement by an ordinary galvanometer of high frequency electric currents or oscillations, where any form of mechanical or electrolytic rectifier is useless.

I construct the bulbs with two or more sets of carbon filaments.

One set when rendered incandescent forming one electrode of the valve and the other set kept cold, the other electrode.

In place of carbon filament for the cold electrodes I use sometimes, loops of platinum wire or platinum wires with plates on the end.

In making the connections of the bulb to the alternating current circuit it is essential to join one end of the galvanometer wire to that terminal of the hot carbon filament to which the negative end of the local or heating battery is applied.

The other end of the galvanometer and the two ends or all the ends of the cold filaments taken together constitute the terminal of the indicating appliance.

The carbon filament may also be heated by part of the alternating current which is being rectified or measured.

Any other method of heating one or more of the carbon filaments may be employed.

The above described multiple carbon filament bulb and a galvanometer may be used as a receiving instrument in wireless telegraphy.

For this case, the aerial receiving wire has the primary circuit of an oscillation transformer inserted in it and one of the above described electrical valves and a galvanometer are inserted in the secondary circuit.

The feeble alternating currents excited in the aerial by electric waves, then make themselves evident by indications in the galvanometer.

Dated this 16th day of November 1904.

J. A. FLEMING.

COMPLETE SPECIFICATION.

"Improvements in Instruments for Detecting and Measuring Alternating Electric Currents."

I, John Ambrose Fleming, of University College, Gower Street, in the County of London, Doctor of Science, do hereby declare the nature of this invention and in what manner the same is to be performed to be particularly described and ascertained in and by the following statement:—

Such instruments as the latter are not affected by alternating electric currents either of high or low frequency which can only be measured and detected by instruments called alternating current instruments of special design. It is, however, of great practical importance to be able to detect feeble electric oscillations, such as are employed in Hertzian wave telegraphy by an ordinary movable coil or movable needle mirror galvanometer. This can be done if the alternating current can be "rectified", that is either suppressing all the constituent electric currents in one direction and preserving the others, or else by changing the direction of one of the sets of currents which compose the alternating current so that the whole movement of electricity is in one direction. Many means have been devised and are in use for rectifying low frequency alternating currents, such as are used in electric lighting. There are well known forms of mechanical rectifier, also there is a well known form of electro-chemical rectifier depending on the fact that when a plate of carbon and aluminium is placed in any electrolyte which yields oxygen on electrolysis, an electric current can only pass through this cell in one direction if below a certain voltage.

Both these forms of rectifier are however inapplicable for high frequency currents. I have found that the aluminium-carbon cell will not act with high frequency currents.

I have discovered that if two conductors are enclosed in a vessel in which a good vacuum is made, one being heated to a high temperature, the space between the hot and cold conductors possesses a unilateral electric conductivity, and negative electricity can pass from the hot conductor to the cold conductor but not in the reverse direction.

As the hot conductor should be heated to a very high temperature say near to the melting point of platinum (1700° C.), it should be of carbon preferably in the form of a filament such as is used in any ordinary incandescent electric lamp. The cold conductor may be of many materials, but I prefer a bright metal such as platinum or aluminium or else carbon.

The two conductors are enclosed in a glass bulb similar to that of an incandescent lamp, and I generally heat the carbon filament to a high state of incandescence by a continuous electric current, the electrical connection to the filament and the cold conductor being made by platinum wires, sealed air tight through the glass.

Figure 1 is a full size sectional elevation of an instrument constructed according to this invention, the electrical connections being shown diagrammatically. Figure 4 illustrates the application of the invention to wireless telegraphy.

Figures 2 and 3 show modifications to smaller scales.

In Figure 1 *a* is a glass bulb, and *b* is a carbon filament like the carbon of an incandescent lamp, suitable say for taking a current of [illegible]

c [illegible] is a cylinder of aluminium open at the top and [illegible] surrounds but does not touch the filament. The cylinder *c* is supported by [illegible] and the ends of the filament *b* are connected [illegible] The platinum wires are sealed in the ordinary manner.

A high vacuum should be obtained in the bulb *a* and as a considerable [illegible] are occluded in the conductors these should be heated when the bulb is being exhausted. The filament *b* can be conveniently heated by passing a current through it whilst the cylinder *c* can be heated by surrounding the bulb with a resistance coil through which a current is passed the whole being covered in a box lined with asbestos or the like. When as hereinafter described the cylinder *c* is replaced by any form of conductor which can be heated by passing a current through it this method is usually more convenient than that just described.

The carbon filament is made highly incandescent in the usual way by a continuous electric current produced by the battery *h* the negative pole of which is connected to the wire *e* and the positive to the wire *f*. The wires *e* and *f* are

connected together by a wire *g* which completes the circuit through the secondary winding *k* of an induction coil (such as is ordinarily used in wireless telegraphy) and a galvanometer *l*. *m* is the primary winding of the induction coil having one end connected as is usual to an aerial wire *n* and the other to earth *o*. The arrangement described above operates as an electric valve and permits negative electricity to flow from the hot carbon *b* to the metal cylinder *c* but not in the reverse direction so that the alternations induced in the coil *k* by the Hertzian waves received by the aerial wire *n* are rectified or transformed into a more or less continuous current capable of actuating the galvanometer *l* by which the signals can be read.

Although Figure 1 shows the application of the instrument to wireless telegraphy it will be understood that the aerial wire *n* may be replaced by any circuit in which there is an alternating electromotive force, whether of low frequency or of high frequency.

I may increase the effect in the following manner: I employ two bulbs arranged as shown in Figure 2 each being similar to that shown in Figure 1. *p p* are the two coils of a differential galvanometer connected to the bulbs in such fashion that currents flowing in opposite directions through the two bulbs, flow in the same direction round the two coils of the galvanometer as regards the needle *q* of the galvanometer itself. For this purpose the hot conductor of each bulb is connected to the cold conductor of the other, hence, one bulb permits negative electricity to flow only in one direction and the other bulb permits only negative electricity to flow in the opposite direction through it. The common terminal of the two galvanometer coils *p* is connected to the coil *k* or any source of alternating electromotive force or of electrical oscillations, the other terminal of the said source being connected to the bulbs as shown. Each bulb has its own separate insulated battery *h* for heating its hot filament.

Under these circumstances, alternating electric currents are split into two continuous currents passing through the two bulbs in opposite and, in the two coils of the galvanometer, in the same directions.

By thus using a differential galvanometer I make use of the whole of the energy of the alternating current instead of discarding half of it. In this manner very feeble electrical oscillations can make themselves apparent by the indication which they give on a sensitive mirror galvanometer.

A number of these valves may be associated together in parallel as shown in Figure 3 so that alternating currents rectified by them separately may produce continuous currents which are added together.

In place of using a metal cylinder surrounding a carbon loop filament, I sometimes use a number of carbon filaments. Some of these are heated by means of an electric current, and become the hot conductor of the oscillation valve and the others remain cold and form the cold conductor. Or the metal cylinder may be replaced by a cylinder of meerschaum or the like having wound helically upon it a narrow ribbon of metallic foil.

The galvanometer *l* may be replaced by any other instrument for detecting the oscillations or by a relay for actuating a detecting or recording instrument.

In those cases in which a larger alternating current has to be dealt with, the hot conductor may be a rod of soft graphitic carbon held in suitable supports.

I find it possible by means of the device described above to rectify an alternating current without the use of any auxiliary continuous heating current. Thus, if I pass through the carbon filament an alternating current to bring it to bright incandescence, I find it I connect either terminal of the filament by a circuit outside the bulb with the terminal of the embracing cylinder or other cold conductor, then in this circuit a continuous current flows. Hence, the device may be used for rectifying either high frequency or low frequency alternating currents of electrical oscillations, provided these are of sufficient strength to render a carbon filament brilliantly incandescent.

Instruments for Detecting and Measuring Alternating Electric Currents.

Having now particularly described and ascertained the nature of my said invention and in what manner the same is to be performed I declare that what I claim is:—

1. A vacuous vessel having in it two conductors adjacent to but not touching each other, one of them being heated, these conductors being connected by a circuit outside the vessel, such circuit being exposed to some influence tending to produce an alternating current in it and which contains a galvanometer or other instrument for detecting a continuous current substantially as described.

2. In instrumen's such as are covered by Claim 1, heating the conductor by means of a continuous electric current passed through it substantially as described.

3. The application of the instruments covered by Claims 1 and 2 to wireless telegraphy substantially as described.

4. Duplicating the instruments covered by Claims 1, 2 and 3, by connecting the two coils of a differential galvanometer respectively to the heated conductor in one vessel and the unheated conductor in the other, the connection between the two coils being connected to the other pair of conductors substantially as described.

5. Instruments for converting alternating electric currents into unilateral currents substantially as described.

Dated this 1st day of August 1905.

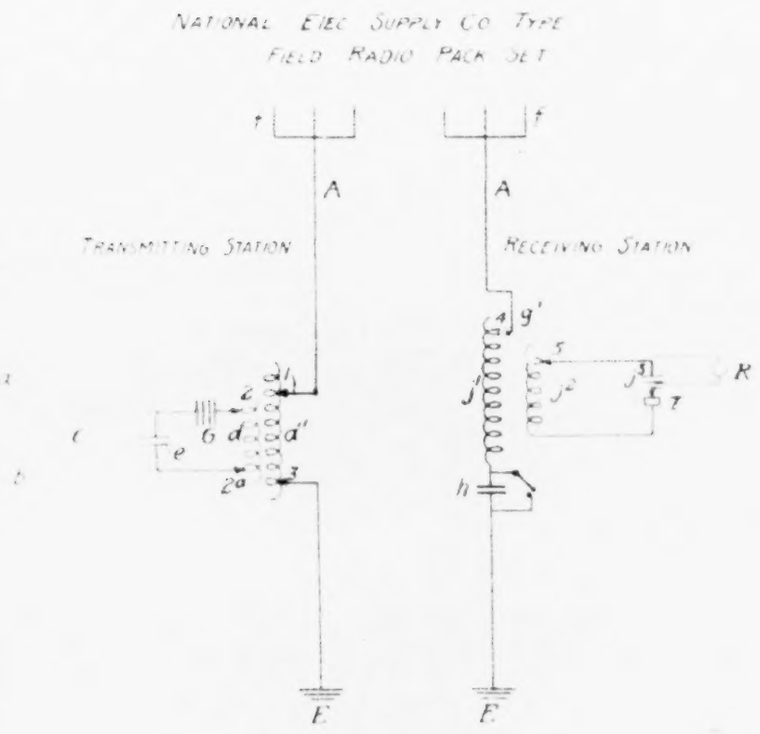
Plaintiff's Exhibit 80



[fol. 2376] PLAINTIFF'S EXHIBIT #84, OFFICIAL INSTRUCTIONS FOR USE OF ULTRA AUDION

Subject: The Ultraudion—Its use with the various models of the 1-P-76 receivers in the U. S. Navy Radio Stations on board ship and on shore.

1. The Ultraudion, or oscillating audion, is very much more sensitive than the best crystal detector. Its great superiority over the ordinary detector, in both uniformity and sensitivity, more than makes up for the few new difficulties that will be met in learning to operate it. All the connections of the Ultraudion are given in the attached diagram. The three tables at the end of these instruction sheets give the approximate ranges, for the three models of the 1-P-76 receivers, within which the Ultraudion will oscillate, and also the size of the loading coils and parallel condensers that will be necessary when working on the very long wave lengths. The measurements were made on an antenna with a fundamental wave length of 440 meters and a capacity of 0.00126 mfds., which is fairly representative of the ordinary ship's installation. When the audion is connected as shown in Figure 1, it is many times more sensitive than the old audion connection, even when it is not in the oscillating condition. When not oscillating it also preserves the distinctive note of a spark station but will not make sustained oscillations, such as are given out by an arc or a high frequency machine, audible.

Description of the Audion

2. The audion has three elements which are sealed in the bulb. They are the filament, one pair of grids and one pair of plates. The connections to these elements are brought out in four wires, two of which are for the filament, while the other two are one for the pair of grids and one for the pair of plates. The lead to the plates is red while the lead to the grids is green. An easy way to remember the grid connection is that G stands for grid and green. The filament is lighted by a 6-volt storage battery, the voltage being regulated by means of a series rheostat. The filament is rated at 3½ volts and about ¾ amperes.

Description of the Ultraudion Circuit

3. The receiving circuit itself consists of two parts, the primary or the antenna circuit, and the secondary or the

inductively coupled circuit. The primary circuit is the ordinary circuit as found in the various models of the 1-P-76 receivers. A condenser in series with the antenna is shown in the diagram. When used in this position more [fol. 2377] inductions will have to be cut in. It is best to use a variable series condenser with a total capacity of 0.001 mfds. When receiving sustained oscillations the series condenser will actually strengthen the signals, and while it is not so good for spark signals it allows a finer adjustment of resonance than would be possible with inductance varied in steps. For wave lengths longer than the range of the primary inductance it will be necessary to put this condenser in parallel with the antenna, but doing this will decrease the strength of signal especially when the parallel capacity is large.

4. In the 1-P-76 1912 model and 1-P-76 improved model the two leads to the ultraudion circuit are connected to the secondary inductance binding posts which are also common to the condenser. The telephone and the detector connections on the sets are left *open*. In the 1-P-76 1914 model there are two fixed secondary condensers, one for the short wave and one for the long wave coils. These condensers are connected to the slide rods of the two secondaries, and will have to be disconnected and a double pole, double throw knife switch mounted on the end of the receiver case. To one set of clips on the switch connect the slide rods of the short wave secondary; to the other set of clips connect the long wave secondary rods and to the pivots of the switch connect the outside variable tuning condenser of about 0.0018 mf.

5. The ultraudion circuit has two leads running to it. One of them is connected directly to the plate or R binding post while the other is connected to the grid or G binding post through the variable condenser GC of about 0.001 mfds. total capacity. The condenser must be in this lead and not in the plate lead. Six binding posts on the audion box are used. The two marked S_1 S_2, "To tuner," or Ra Re, are not to be used. The R, G, A-, A-, and the two telephone posts are sufficient as the diagram shows. The bridging condenser BC is connected from A- to the R post, and should have a total capacity of 0.002 mfds. and be variable. Connect the telephones in the posts marked "Telephones" on the audion box. The circuit is now ready for use.

Method of Obtaining Oscillations

6. Draw secondary inductance out as far as possible from the primary.

(2) Set secondary tuning condenser C at 0°.

(3) Set bridging condenser BC at 0°.

(4) Cut in 80 turns of secondary inductance for either of the 1912 models of 1-P-76, or 30 or 40 turns of the 1914 model short wave secondary.

(5) Set the grid condenser GC at 40°.

(6) Bring filament to a fair brightness.

[fol. 2378] (7) Vary B battery step by step and tap with the finger on the inductance side binding post of the grid condenser, or at the point shown in the diagram. When the bulb is in the oscillating condition a click will be heard in the telephones when the finger touches the post and another when the finger is removed. The tapping should be very frequent and the condensers should be kept *very* close to the points mentioned above. As you tap vary the A and the B battery voltages. The oscillating point is but very little below the point where the blue arc appears. On wave lengths up to 1500 meters the bridging condenser should never be raised above 10°, neither should the grid condenser be below 15°. On account of the high resistance of the secondary inductance not more than 30° can be used on the secondary condenser with the best bulbs, and often not more than 10°. This applies to the 1912 models of the 1-P-76 where the capacity of the condenser is about 0.0018 mfds. This size of condenser is also large enough for the 1912 model 1-P-76.

7. There are two good ways of determining whether a bulb is in the oscillating condition. The first is by hearing the double click mentioned above. The second method is the use of a testing buzzer. If the bulb is oscillating the cellar note of the buzzer will be roughened. If the oscillations stop they can generally be restarted by bringing the secondary tuning condenser back to 0°.

A Device for the Prevention of Deadening of the Bulb Due to Strong Signals and Static Shocks

8. In figure 1 there is shown a double carborundum contact which connected across the grid and the filament. The object of this contact is to prevent the killing of the bulb

due to very heavy signals and some kinds of static shocks. It will be necessary to use it in stations where strong interfering signals are met with and in fleet work. It is not intended as a static preventer. Any carborundum can be used and the contact need not be light; in fact, there is not much choice in the contact.

Causes of Failure to Produce Oscillations

9. Some bulbs will not oscillate so it is best to try several, remembering to vary the A and the B battery voltages. Vary the condensers *slowly*. Sometimes reversing the R and the G leads of the bulb will clear up the trouble because frequently bulbs are found that have reversed leads. Another trouble is indicated by failure to produce a blue arc. If it is impossible to strike the blue arc the trouble lies in the B battery not having sufficient voltage, or the connections are wrong, or the bulb is improperly exhausted. B battery trouble is located by varying the voltage and if sharp clicks are not heard, provided connections are per [fol. 2379] diagram, the voltage of the battery should be tested, and where the test is not satisfactory look for poor cells, and short circuit those that do not come up to voltage. The cells deteriorate through local action rather than through use, so that old cells are more likely to cause trouble than fresh ones. If the trouble is not in the B battery look over the connections, carefully inspecting them for contact and proper position. For example, if the GC is in the plate lead no oscillations can be produced. The condensers used in this work should have the movable section connected to its binding post by means of a flexible lead so that good contact will be certain.

10. When once oscillations are produced note the settings of the condensers and the inductance. Familiarize yourself with the muffled double click and vary the secondary condenser, tapping all the while to see when the oscillations cease. On short wave lengths B battery must be used at a higher voltage and the A battery voltage also will have to be changed. At the longer wave lengths these two may be reduced, although this depends a great deal on the state of the bulb. It has been found that when a bulb has been burned for some time that it will oscillate more freely than when new. The bridging condenser generally need not be varied much from the 0 setting, the capacity due to the

edge effect of the condenser plates being sufficient except when working long wave lengths. The amount of bridging condenser necessary varies greatly with different bulbs. In the appended tables an average bulb was used, so the values given are fairly representative of general conditions. Do *not* use too close coupling between the primary and the secondary circuits for the oscillations will cease with a click as the coupling is increased. In case close coupling is used while trying to get the bulb to oscillate it is doubtful whether the oscillations can be started on account of the large amount of resistance that is added to that of the secondary inductance due to coupling alone. The closest point that can be safely used without the bulb stopping its oscillations can be found by observation.

11. Audibility readings can be taken by placing two pairs of telephones in series in place of the one pair, the audibility box being connected across the pair of telephones on which the readings are to be taken.

The Ultraudion Used as a Detector for Spark Signals Only

12. Frequently it is desirable to preserve the distinctive note of a spark transmitter when receiving. The Ultraudion, when in the oscillating condition, changes the spark note to a rough note, the roughness of the note depending on the spark frequency and the amount that the receiving circuit is detuned. Although the Ultraudion is [fol. 2380] in its most sensitive condition when oscillating, yet the note produced is difficult to read under static conditions. If either the stopping or the bridging condenser is varied a point will be found where the distinctive spark is brought in. This point can be found by trial. The oscillations are preferably stopped, or prevented, by keeping the bridging condenser large. The Ultraudion in the non-oscillating condition is at least twenty times as sensitive as the audion detector.

The DeForest Amplifone

13. The best place to connect the amplifone is in series with the pair of telephones of the ultraudion circuit. It has been found that one step of amplification is all that can generally be used. Although greater increase can be obtained with two and three steps the corresponding increase

of amplifier noises and static is so great as to more than counterbalance the increase of signals.

14. The binding posts marked S_1 S_2 are the connecting points for the amplifone. Connect one post S_1 directly to one of the telephone binding posts of the ultraudion and connect from the other telephone post through the telephones to the S_2 post. A description of the amplifone and its operation was issued by the Department, September 30, 1914. Audibilities can be taken of the amplified signals by connecting the audibility box across the telephones of the amplifone.

The Telephone Transformer

15. The telephone transformer is used primarily to reduce interference from arc stations operating on about the wave length that is being received. When using this transformer a station can be read when the wave length is only 6% off the interfering wave length. This applies to arc signals. The gain in selectivity is not so great when a spark station is being received. It also helps in reducing static disturbances as the coupling of the transformer can be varied and, although the loudness of the signals is decreased, the static is generally so considerably decreased that signals can be read without the transformer would be too much broken up to read.

16. The transformer (see Figure 2) consists of a primary and a secondary. The primary has a low resistance and will need to be connected in series with the telephones of the ultraudion circuit, that is, the telephones and the primary take the place of the ordinary receiving telephones of the circuit. The secondary of the transformer is tuned roughly by means of a tuning condenser C of from 0.01 to [fol. 2381] 0.10 mfds. capacity placed in series with the secondary of the transformer. This condenser can be a mica dielectric condenser which is variable (x) by 0.01 mfds. steps. The telephones are connected across this capacity with a condenser C_1 in series with them. The series condenser can be from 0.005 to 0.02 mfds. and variable (+0.005

(x) If variable condensers are not to be had, making C about 0.01 mf. and C_1 0.02 mf. will tune the circuit for receiving a tone of about 1,000 vibrations per second.

mfds. steps. The two coils slide on an iron wire core so that the coupling can be varied.

Specifications of the Transformer.

17. Primary spool:—Core is made of fiber tube that is 1 inch inside diameter, $2\frac{1}{2}$ inches long. Heads are $\frac{1}{4}$ inch thick and $3\frac{1}{2}$ inches in diameter. Distance between heads is 2 inches. Wind 40 layers of #28 B&S SCC wire. Bring out the beginning and the end of the winding for connection.

18. Secondary spool:—Core is made of fiber tube that is 1 inch inside diameter, $3\frac{1}{2}$ inches long. Heads are $\frac{1}{4}$ inch thick and $2\frac{1}{4}$ inches in diameter. Distance between heads is 3 inches. Wind 18 layers of #26 B&S SCC wire. Bring out the beginning and the end of the winding for connection. The resistance of the coil is about 50 ohms.

19. Core:—8 inches long and of such a diameter as to allow the two coils to slide easily over it. Iron wire or silicon-steel strips are satisfactory for this core.

Method of Using the D. C. Lighting As a Substitute for the B battery of the Audion

20. The drawback in the use of the ordinary D.C. supply for audion work lies in the fact that the noises of commutation drown out weak signals and otherwise interfere with the reception of signals. These noises can be overcome, for the most part, by means of suitable chokes inserted in the two leads of the D.C. supply. Since the B battery is the chief cause of audion trouble and failure to operate a method of using the D.C. supply has been worked out. Construct the two choke coils in the following manner:

21. The cores are made of fiber tubing $1\frac{1}{4}$ inches outside diameter with $\frac{1}{8}$ inch walls and 3-15 16 inches long. The heads are $\frac{1}{4}$ inch thick and $3\frac{1}{2}$ inches in diameter. [fol. 2382] Fasten two heads to each of the cores, thus making two spools that have a winding space of 3-7 16 inches. On each spool wind 32 layers of #23 B&S DCC copper wire. The layers average 112 turns, making 3600 turns on each coil. The resistance of the coils is 43 ohms apiece. Bring out the beginning and the end of the connections. Mount the spools when wound on a closed iron core that has a square section and a square shape. In this manner the inductance,

or the choking effect, will be increased without an excessive amount of wire being used.

22. Connect the chokes, one in each leg of the D.C. circuit, so that the choking effect will be equalized. Connect the potentiometer across the chokes. The potentiometer should be able to carry $^3/_4$ amperes and give a voltage range of at least 30 volts. The low voltage connections of the potentiometer are connected, one side to the B-binding post of the audion box while the other is connected to the B binding post. Of course, battery B will have to be entirely disconnected from the circuit when the D.C. is being used. The chokes should be connected so that they help each other in magnetizing the core. If the magnetism of the core is weak and one pole is dead the coils are opposing. When the poles are all equally strong the coils are helping and the magnetism is strong.

Tables of the Ranges of the I P 76 Receivers of the U S Navy

23

I P 76 1912 Model.

Lowest number of secondary turns for oscillations is 80.
Wave lengths 700 to 1050 meters.
C from 0° to 15°.
GC from 15° to 40°.
BC at 0°.

160 turns.

Wave lengths 1200 to 1700 meters.
C from 0° to 15°.
GC from 20° to 40°.
BC at 0°.

320 turns.

Wave lengths 2800 to 3100 meters.
C from 0° to 20°.
GC from 15° to 40°.
BC from 0° to 10°.

I P 76 1912 Improved.

Lowest number of secondary turns for oscillations is 80.
Wave lengths 500 to 900 meters.
C from 0° to 30°.
GC from 15° to 40°.
BC at 0°.

160 turns.

Wave lengths 850 to 1850 meters.
C from 0° to 60°.
GC from 30° to 50°.
BC at 0°.

320 turns.

Wave lengths 1250 to 2900 meters.
C from 0° to 60°.
GC from 20° to 40°.
BC from 0° to 10°.

[fol. 2383]

Constants for raising to 5000 meter wave length by means of inductance; secondary 14° of the tuning condenser with 320 turns cut in and a 5.0 milli-henry loading coil in series with it.

Primary circuit: All the inductance of the set and 2 milli-henries in series with the primary circuit. Raising to 5000 meter wave length by means of parallel capacity in the antenna circuit. About 110° of the 0.001 mfd. parallel condenser. With the 5.0 milli-henry coil the secondary will oscillate over the entire range of the capacity of the tuning condenser. Wave lengths are from 2500 to 6400 meters.
GC from 15° to 20°.
BC from 20° to 35°.

Constants for raising to 5000 meter wave length by means of inductance; secondary condenser can be used from 9° to 100° when a 5.0 milli-henry loading coil is cut in series with the 320 turns of the secondary. Wave lengths are from 1800 to 6000 meters. GC 15° to 30°. BC 80° for maximum on the long waves. primary circuit with 2 milli-henry loading coil will tune in 5000 meters. By means of a parallel primary capacity use all the primary coupling coil and 40 turns of the loading coil of the set and about 130° of the 0.001 microfarad capacity. With 8 milli-henries of primary load in addition to the entire primary and a series 0.001 microfarad capacity cut in to 135° strong signals and sharp resonance points can be obtained.

Note. When a series condenser in the antenna circuit is used and the antenna loaded with inductance to produce a stiff circuit the resonance point of the primary and the secondary circuits is found by means of a sharp click as the resonance point is passed in either of the two circuits. This is especially true when the longer wave lengths are being used. On the shorter wave lengths a faint click is sometimes heard although it is not always dependable.

I P 76 1914 Model.

faces are corroded or pitted, but that when kept air tight they are worn smooth and clean by the sparking action. Sometimes, if there is a flaw in one of the plates or if air leaks into the gap, there will be a noticeable drop in the antenna current, and the note will become poor. When it is believed that the trouble is confined to one or two gaps it is possible to continue sending without dismounting the whole gap by short-circuiting the bad gaps by means of clips provided for the purpose, in which case as many new gaps must be put into circuit by adjusting the movable clip to the right as were cut out by the short-circuiting clips.

The gap should be dismounted *only* when the trouble has been located in the gap and it has been found impossible to remedy it by short-circuiting the different gaps in use. The gap should be dismounted only by an experienced man, who should clean the [illegible] by rubbing them face down on fine emery cloth or paper on a *flat surface*. It is absolutely necessary that both the bearing surfaces and the sparking surface be kept true and plane, as shown by a straightedge.

Great care should be exercised in reassembling the gap to set the mica washers accurately on the annular surfaces of the disk and to put on enough tension with the clamping screws to render all of the gap spaces air-tight.

TUNING OF SENDING SET.

The tuning of the closed and open circuits to resonance, and the determination of the correct coupling between them are the two most important adjustments in a quenched spark transmitter. In the present type of directly coupled set with a flat spiral as the oscillation transformer, these adjustments can be made either with or without the help of a wave meter. If made without the meter the adjustments are more difficult and must be found by trial, but they should satisfy the following tests: (1) The number of turns in the closed circuit should be chosen so as to give the desired wave length; (2) the antenna hot-wire ammeter should show the maximum reading that can be obtained by adjusting the number of turns in the open circuit according to the table on page 104; and (3) the note as heard in the telephones of the receiving set should be clear and free from [illegible] of the spark. The [illegible] is to a great degree dependent on [illegible] when an incorrect change in one set will affect [illegible] the result when changing [illegible]

Instructions For Operating The Field Radio Pack Set, Model 1912.

The 500-cycle, quenched spark radio transmission set and inductively coupled receiver constituting the 1912 model field radio pack set of the Signal Corps, were adopted after extensive investigation of modern methods in the practice of radio telegraphy. The weight efficiency has been more than doubled without decreasing the effective range of radiation. A brief description of the equipment with instructions for the care and operation of the set follows:

Drawings

The following drawings will form part of and illustrate this bulletin:

Field radio pack set, model 1912, receiving circuit diagram 911a
Field radio pack set, model 1912, sending circuit diagram 911b
Field radio pack set, model 1912, poles for shelter tent 911c

Generator

The generator is an 18-pole, alternating current machine of 125 watts capacity at 110 volts and 500 cycles, designed for an armature speed of 3333 R. P. M., the ratio of the gearing being such that this speed is obtained when the crank handles are revolved at 36 R. P. M. A separate direct current exciter is mounted on the main armature shaft for energizing the field magnets.

A double speed clutch is provided on the fly wheel which when properly regulated should engage the armature gear at a speed between 30 and 34 R. P. M. of the crank handles and disengage same when the crank handle speed exceeds 37 R. P. M. Adjustment of the over-speed clutch is made by means of the two radial screws on the periphery of the steel fly wheel which are locked by set screws on the inner face of the wheel; loosening the screws causes the over-speed clutch to operate at a lower speed, and, conversely, tightening this screw causes it to operate at a higher speed.

at each alternation, in which case the fault can be remedied by reducing the number of gaps. If the adjustment is such that the condenser is discharged regularly at every second or third alternation, the note will be even but low pitched, somewhat similar to the note produced by an unquenched spark gap. If the generator speed is constant at 500 cycles, reducing the number of gaps will probably remedy the trouble, although it may be necessary to "loosen" the coupling. By loosening the coupling is meant to reduce the number of turns of the linking spiral (oscillation transformer) common to both the closed and radiating circuits, or, if no common turns are being used, to increase the distance between the sections included in the "closed" and "radiating" circuits.

Damping

When the current in the closed oscillating circuit dies out after a few reversals as already described, the oscillations are said to be "damped". The proper amount of damping is indicated by a high pitched, musical note. Damping is aided by close coupling; however, if the coupling is too close, a retransfer of energy from the radiating to the closed oscillating circuit may occur, with an induced E. M. F. sufficient to again break down the spark gap. This condition can be detected by its effect on the note which will be lower pitched and ragged.

The remedy is to loosen the coupling. In tuning sending circuits, the operator may ascertain the character of the note emitted by listening on the telephone of his own receiving set, which while disconnected at the control switch will be sufficiently energized by the field of the sending helix or oscillating transformer to produce the note.

Receiving Set

The receiving set consists of an inductively coupled transformer, perikon detector, series and stooping condenser, with terminals, switches, etc., mounted in an oak case with hard rubber top and front and is supplied with a Sullivan type, high resistance, double head telephone receiver, as indicated in drawing 911a.

[fol. 2411] The primary coil of the transformer is wound with 170 turns of No. 22 enamelled copper wire divided into two sections, one of 10 turns and one of 160 turns. Each single turn of the small section is tapped off and the leads

connected to the terminals of the dial switch numbered from 1 to 10. The large section is divided into 16 groups of 10 turns each and the leads connected to the terminals of the dial switch marked from 10 to 160. As these dial switches are connected to a common zero point with the switches working in opposite directions from this point, as shown in the diagram, the total number of turns included can readily be determined, being the sum of numbers indicated by the two switch arms.

A condenser of small capacity is connected in series with the aerial and is provided with switch for shunting or short circuiting same when not in use. This condenser is intended for the reception of wave lengths of two hundred meters or less, and is normally short circuited when longer waves are being received.

A small detached buzzer is provided for testing purposes. This buzzer, when operated in the vicinity of the aerial, counterpoise leads, or windings of the coils, excites feeble oscillations which enables the operator to adjust his detector efficiently before tuning the primary and secondary circuits.

Tuning of Receiving Set

After adjusting the detector to a sensitive point by the aid of the test buzzer, move the secondary coil into the primary as far as it will go and set the secondary dial switch on, say 200, which will answer for wave lengths between 250 and 700 meters. Then vary the dial switch marked from 10 to 160 until the signals are heard; this will probably be found near the contact marked 60. When the signals are heard, the adjustment is continued by varying the primary and secondary dial switches and the position of the secondary within the primary coil (i. e. the "Coupling", which for wave lengths approximately 400 meters will be between 10 and 20 on the Coupling scale) until the maximum sound is heard in the telephones. If the incoming wave is found to be short the small 2-point condenser switch may be set at the "On" position which places the condenser in series with the aerial.

Shelter Tent

This tent is similar in dimensions and construction to the standard "Common" tent issued by the Quartermaster's Department, but is made of lighter duck and is not provided with ridge poles nor uprights. Three extra sections are

[fol. 2412] furnished with each 40 foot mast and it is intended that these will be substituted for the tent ridge and upright poles. Two extension pieces are supplied for adapting one extra section as ridge pole and two wood plugs with spikes are supplied for adapting the other two sections for use as uprights. These are shown in the accompanying sketch together with ridge poles and upright assembled for setting up.

Insulating Device

A device is provided for use in insulating the aerial when the shelter tent is used in damp weather, consisting of a square piece of sheet rubber with small marginal holes for lacing into the ventilator at either end of the tent, and a tube attached to the center for admitting the aerial lead. When in use, sufficient slack should be left in the aerial lead to form a drip loop outside of the tent, and if found necessary a piece of heavy insulated wire can be used as a leading in wire.

Packing

In packing the set on the pack frame, the fourteen wood tent pins and four extension pieces should be folded in with the shelter tent; the insulating device, iron guy pins, hammers, crank handles and oil can placed in the accessory bag. The gear wheel with its leather case, antennae and counterpoises are carried in the large canvas bag. Two end guys are furnished with each tent, which, in case an extra section of mast is broken, will hold the tent in position without using a ridge pole.

The hand generator, generator stand and ten mast sections are carried on one mule; the operating chest, antenna-counterpoise bag and accessory bag on another. The antenna-counterpoise bag is suspended by the "D" rings on the side of the pack frame provided with one set of hooks. The operating chest is hung on the top set of hooks on the opposite side and the small accessory bag beneath it on the lower set of hooks. The tent is carried on top of the frame between the chest and large bag. Two wood foot rests are supplied with each generator stand with sixteen screws for securing them to the adjustable flanges on the base of the stand.

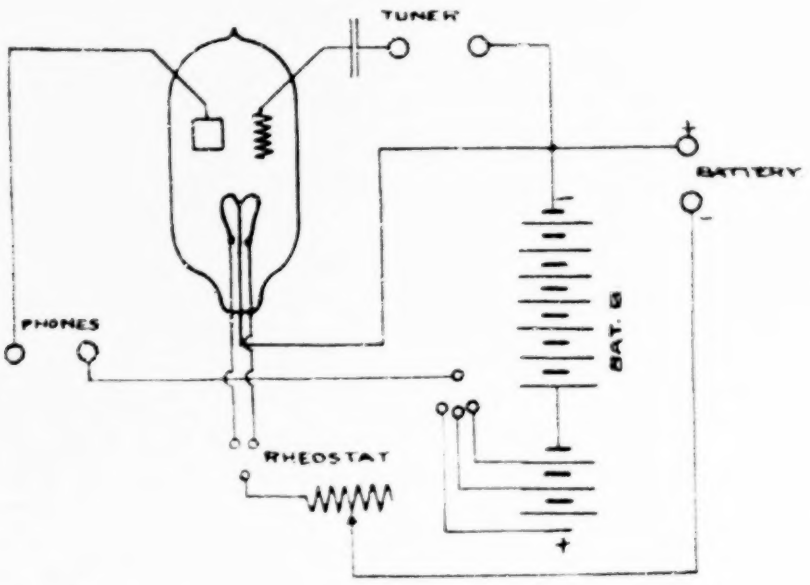
Circuit of Type RJ4 Audion Detector



After the first filament has been consumed wind the little copper wire tight around the brass base of bulb underneath the rubber band. This connects the second filament.

Instructions.

Do not connect over six volts Storage Battery to the external binding post marked + and —. Before lighting the filament see that the resistance switch is on "ALL IN" position. Then adjust rheostat until lamp burns at normal brightness. Adjust brightness of filament and the Battery B switch to give maximum sensitiveness.

In connecting up the Audion Detector, connect the grid to G and wing to W as marked below the binding posts. The Grid is the zig-zag wire terminal. The Wing is the plate.

If bulb is capped the green wire leads to the grid, the red leads to the wing.

RADIO TELEPHONE & TELEGRAPH COMPANY

309 BROADWAY, NEW YORK

Concerning the RJ4 Audion Dectector

The Audion has been proven, by scientific and official tests to be from 1.5 to 3 times as sensitive as any crystal detector. With it even in this small and cheap form, telegraphic ranges far greater than those possible with the crystal or electrolytic detectors are easily attained. There is scarcely an amateur who has tried one but will admit this, and consequently has no further use for his crystal detector.

It is reliable, requires no adjustment after the proper voltage and heating currents are determined, it can not be injured by powerful transmitter sparks in the immediate vicinity. If it momentarily loses its sensitiveness by reason of the transmitter spark, it is automatically restored, without the slightest decrease in its sensitiveness.

If too much "Battery B" voltage be applied a blue glow will appear in the bulb, or tube, or may be seen merely around the edges of the "plate" or wing. When this blue glow fills the bulb it is usually not very sensitive, and can be removed by simply reducing the B voltage by the 4-point switch on front of box. The sensitiveness can be instantly restored by merely switching off and on the lighting current. Only one filament should be burned at one time. This doubles the life of the bulb.

Never burn the filament at excessive brilliancy, as full sensitiveness can be obtained at normal brilliancy.

Alway use a storage battery for lighting the lamp, as dry cells run down very quickly when used for that purpose.

Never use more than three cells of storage battery.

Don't let the storage cells run down low and then hook in another fourth cell, because if this is done there is always danger of the run-down cells picking up, or recuperating after a short period of rest and then of burning out the filament when first switched on again.

Connect the secondary of the receiver tuning circuit to the binding posts marked "Tuner."

It makes some difference in the results obtained which of these two terminals is connected to one or the other of the two "Tuner" binding posts. The surest way of determining this is to reverse the two connections, and thus observe which gives the louder signals.

The RJ4 Audion set is for **Amateur** work only. It is not under any conditions licensed to be used for commercial work.

INTERFERENCE IN WIRELESS TELEGRAPHY

By John Stone Stone

Read before the Electrical Section, 9th March, 1905.

Introduction

Of the various problems which have been presented in the course of the development of the new art of wireless telegraphy, none is of greater interest to the engineer and none is of more far-reaching importance from the industrial and commercial standpoint than that of rendering the receiving instruments of wireless telegraph stations immune from *interference*.

There are two principal kinds of interference:

1st. Interference which arises from electrical charges which accumulate upon the vertical oscillator under various conditions of weather, provided the vertical oscillator has no adequate electrical connection to the earth.

2nd. Interference which arises from such stray electromagnetic waves as are produced by lightning, by magnetic storms, by sparks in neighboring circuits, such for instance as occur in trolley circuits, and also from the electromagnetic waves emanating from wireless telegraph stations other than that with which communication is desired.

Interference Due to Static Charges.

The interference which results from the first of these two sources is readily overcome since the oscillator of a wireless receiving station may always be given a metallic connection to the earth sufficient to maintain it clear of statical charges without in any appreciable degree interfering with its operation as a receiving oscillator.

Thus for instance if the vertical oscillator includes a condenser insulating a portion of the vertical oscillator from the earth, the condenser may be shunted by a coil of inductance so large that

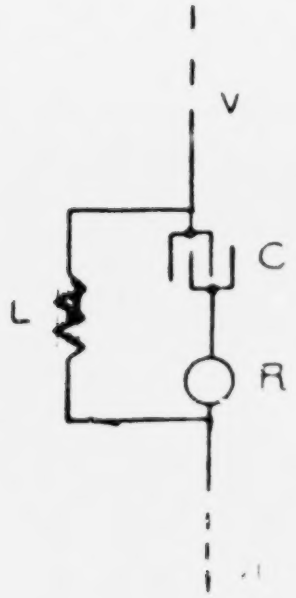

Fig. 1.

for the high frequencies employed in wireless telegraphy it will operate practically as an open circuit, whilst affording a ready path to earth for the electrical charges which, in its absence, would accumulate upon the vertical oscillator and produce disruptive discharges to earth.

Again, if a highly sensitive detector or receiving device be included directly in the vertical receiving oscillator, such an inductance coil may be placed in shunt to the receiver without appreciably affecting its sensitiveness. The coil will then serve as a by-path for the currents due to the passage of the charges of the vertical oscillator to the earth.

Another device which may serve to still further protect the receiver under these conditions is that illustrated in Fig. 1, in which

V and V' are portions of the vertical oscillator system, L is a coil of large inductance, R is the receiving device, and C is a condenser of capacity so large as not to impede appreciably the passage of the high-frequency oscillations of wireless telegraphy while acting practically as an open circuit for the more slowly varying currents by which the vertical oscillator is maintained free of static charges.

The greatest security from this form of interference is however obtained by providing the vertical receiving oscillator with an adequate conductive connection to earth and by placing the receiving device in a local circuit made resonant by a coil and a condenser to the frequency of the electrical oscillations to which the receiver is intended to respond.

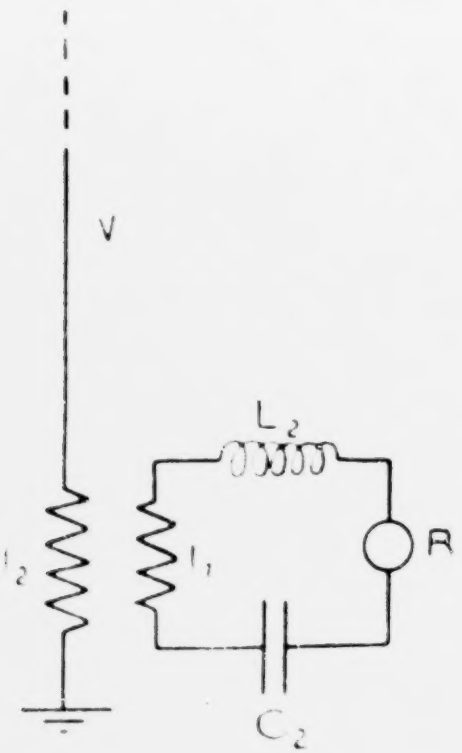

Fig 2

An example of such an arrangement is shown in Fig. 2, in which V L I is the vertical receiving oscillator, I_1 and I_2 are the [illegible] a high frequency transformer, R is the receiver, C [illegible] and L_2 is an inductance coil.

The manner in which the local circuit containing the receiver is made resonant to the frequency of the oscillations to which it is intended to respond will be considered later in this paper. It is

2797

sufficient here to note that the local circuit being resonant to a frequency sufficiently high for the purposes of wireless telegraphy, will not be appreciably affected by the more slowly varying currents in the vertical oscillator by which the latter is maintained free from static charges.

INTERFERENCE DUE TO ELECTROMAGNETIC WAVES.

Coming now to the prevention of interference by electromagnetic waves such as emanate from other wireless stations than that with which it is desired to hold communication, and to the prevention of interference by stray electromagnetic waves, we find that the solution of the problem depends upon the character of the message-bearing wave, the energy of which it is desired to convey to the receiving device, and also upon the character of the disturbing waves, the energy of which it is desired to exclude or divert from the receiving device.

We can control the character of the waves whose energy we wish to receive, by suitably designing the apparatus to be used at the transmitting station, but we have no control over the character of the disturbing waves except in so far as these arise from wireless stations within operative range of the receiving station.

The simplest solution of this problem is to cause each transmitter to send out its signals by means of *persistent trains of simple harmonic waves* of a frequency materially different from that employed by any other transmitter within operative range of the receiving station with which communication is to be maintained and to make each receiver responsive only to *persistent trains of simple harmonic waves* of the frequency employed by the transmitter with which it is in communication.

By this means the system is rendered selective and becomes a multiple system of telegraphy, permitting the operator at each station to select the station with which he wishes to hold communication to the exclusion of all the other stations, and by which a number of messages may be transmitted simultaneously in a given region without interfering with one another.

Since the stray electromagnetic waves arising from lightning etc., are not persistent trains of simple harmonic waves, but partake more of the character of isolated impulses, the receiver in such a system does not respond to such stray electromagnetic waves and it is therefore also freed from interference which would otherwise arise from such sources.

The manner in which a transmitting station is made to develop persistent trains of simple harmonic electromagnetic waves

of one frequency to the exclusion of waves of other frequencies, though simple in itself, in practice requires the strictest attention to certain details, and these may be best understood by the consideration of a concrete case, this being the manner in which such problems are usually presented to the engineer if not to the inventor.

Transmitter.

In modern wireless telegraphy the messages are transmitted by electromagnetic waves which are horizontally polarized at the earth's surface, and which are developed by electrical oscillations set up in an electrical oscillator whose axis is normal to the surface of the earth and which is connected to the earth at its lower extremity.

The reason for employing waves of this type and so developed, is that such waves have, at the earth's surface, no component of electric force parallel to the surface and no component of the magnetic force normal to or cutting that surface, except in the immediate neighborhood of the base of the transmitting oscillator. As a result they do not tend to induce currents in the surface of the earth as they travel away from the transmitter except where the surface of the earth deviates from the plane of polarization of the waves at that surface. The energy which would otherwise be rapidly dissipated through the production of induced currents in the earth is therefore conserved in the waves. Moreover when a deviation occurs between the plane of the earth's surface and the plane of polarization of the waves at the earth's surface, the currents induced in the surface of the earth are such as to bend the wave front into a position normal to the surface with the result that the waves travel over and around mountains and in fact follow the earth's surface whatever be its contour, instead of tending to travel in straight lines like ordinary light waves and as would be the case with vertically polarized electromagnetic waves.

For a more complete exposition of these points see a paper read by the Author at the International Electrical Congress held at St. Louis, Sept. 12 to 17, 1904, and reprinted in the Electrical Review, New York, Oct. 15, 1904.

There is not space in this paper to discuss in detail the development of the waves described above, but their genesis and mode of propagation is clearly suggested by Figs. 3 to 8. Fig. 3 and Fig. 4 illustrate the development of a wave by free electrical oscillations in a straight wire AoB, the curve lines indicating a line of electric force in its various phases from $t=0$ to $t=\frac{1}{8}$ T, where T is the time of a complete free electrical oscillation in the

2791

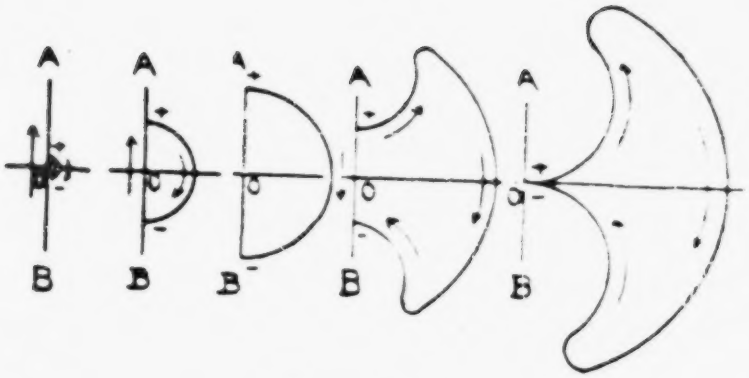

Fig. 3

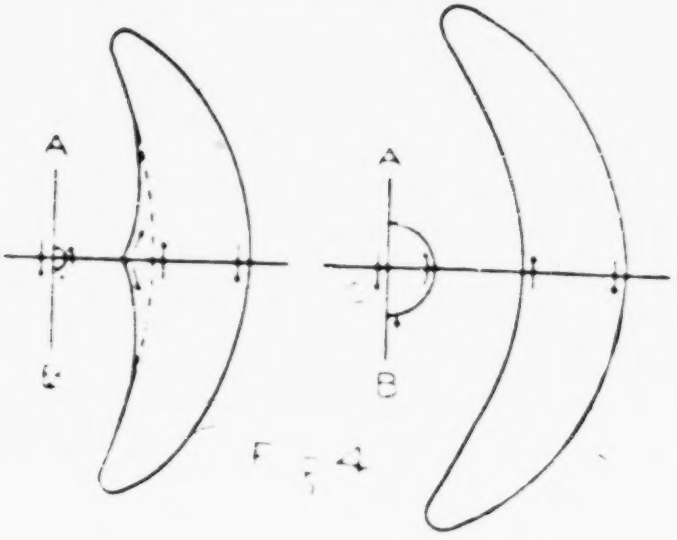

Fig. 5

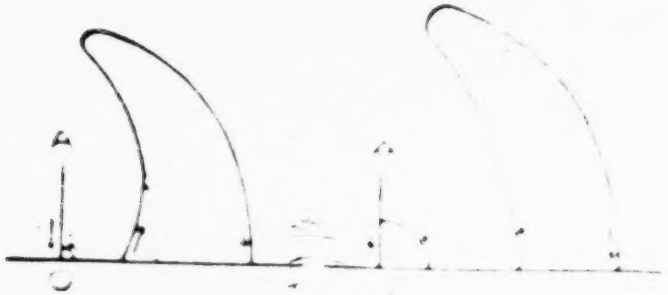

wire. In Figs. 5 and 6 the genesis of a wave from a vertical linear oscillator Ao earthed at its lower extremity is illustrated, and in Figs. 7 and 8 the effect of an elevation and depression in the surface of the earth upon the wave fronts at that surface is indicated.

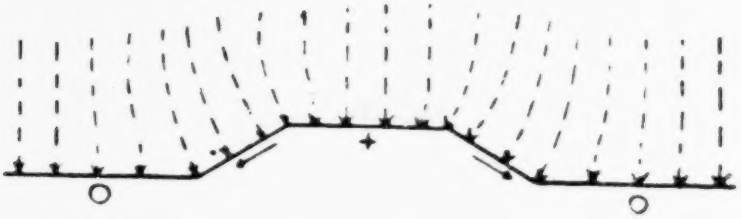

Fig 7

We may next consider the earth connection of the transmitting oscillator and the nature of the support for the oscillator.

Although, by the use of such waves as are described above, normally the current density in the surface of the earth at a distance from the transmitting oscillator is rendered excessively small, nevertheless at, and in the immediate neighborhood, of the base of the vertical oscillator, the current density is in general very great. Moreover since the current is of high frequency, it tends to flow only on the surface of the earth. For this reason the usual

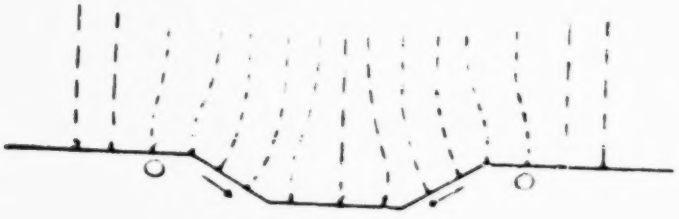

Fig 8

specifications for obtaining a good earth connection, which involves burying a conductor of large area so deep in the ground that it shall be in permanently moist earth, are no longer advantageous, and in a properly constructed wireless telegraph station the conductivity of the *surface of the earth* in the immediate neighborhood of the base of the oscillator is artificially increased by a *superficial ground-plate* composed of sheet metal, or of wire netting, extending radially from the base of the oscillator and covering as large an area about the base of the oscillator as is available for the purpose and consistent with reasonable economy.

Since the waves are horizontally polarized, the supports for the vertical oscillator, such as masts and guy-ropes, should either be of insulating material, or if of metal, they should be divided by insulation into sections short compared to one-half the wave-length of any of the waves to be employed. The reason for this is that the fundamental free period of vibration of a linear conductor is such as to cause it to respond most energetically to waves of twice its own length. For such wave-lengths, therefore, the linear conductor would absorb an undue amount of the energy of the waves and moreover because of the rise of potential which occurs at the ends of the conductor for waves of such length it would be difficult to insulate the conductor from the earth or adjacent portions of the support of the vertical oscillator.

We come now to the vertical oscillator itself. This in general consists of two parts, the elevated conductor *per se* and the devices through which it is connected with the earth.

We shall here consider the relatively simple case in which the elevated conductor is a straight, cylindrical copper wire of length a and radius ρ

Both theory and practice show that the electrical vibrations in such a wire connected directly to the earth at its lower extremity correspond very closely to the transverse vibrations of a heavily damped stretched string.

If such a wire be charged to a high potential and be then permitted to discharge to earth, the electrical oscillations developed in it, and therefore also the electromagnetic waves radiated by it will not be simple harmonic in type and will not be persistent. These waves will not therefore correspond to the sound waves given out by a tuning-fork, but will be of the character of those given out by a heavily damped violin string plucked at its centre.

The fundamental of the waves given out by such an oscillator has a wave-length which very closely approximates four times the length of the wire, and this is accompanied by all the odd harmonics. The oscillations are so much damped by the energy drawn off from the oscillator by radiation as to make the resulting waves more nearly the equivalent of an impulse than of a sustained or persistent train of waves.

If, however, the elevated conductor be not directly connected to the earth, but be connected to it through an inductance coil, both theory and practice show that its electrical vibrations correspond to the transverse vibrations of a heavily damped stretched string with a mass attached to its centre.

The effect of the load at the centre of the stretched string and of the inductance at the base of the vertical wire is to increase the

persistency of the vibrations, to minimize the importance of the harmonics and to lower the frequency of the fundamental. It might therefore seem that in order to cause the vertical oscillator in question to radiate a persistent train of simple harmonic waves of a predetermined frequency, it would be sufficient to charge the

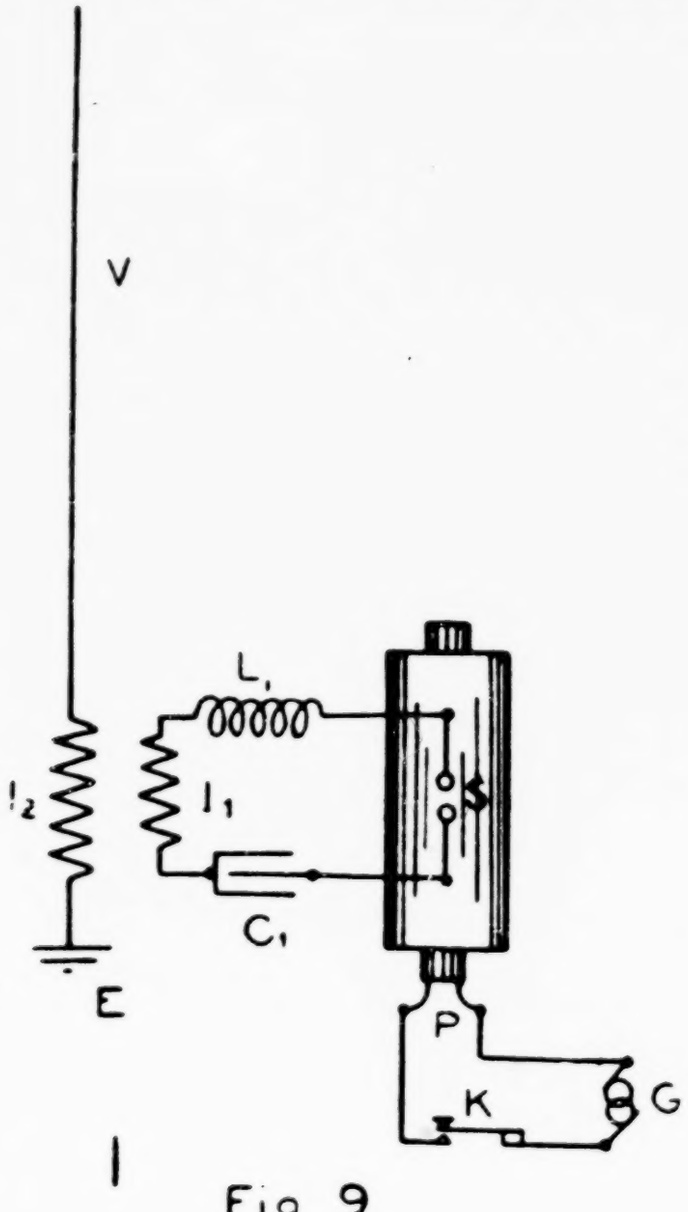

Fig 9

vertical wire to a high potential and permit it to discharge to earth through an inductance coil of suitable dimensions.

This indeed was the plan adopted in the first crude attempts at producing a selective system of wireless telegraphy. This method necessitates the use of waves of much lower frequency than that normally produced by natural vibrations in the vertical wire *per se*.

28013

The degree of persistency of oscillations so obtained however, is not as great as is required in practice. Such persistency as is obtained is gained at the expense of the amplitude of the current oscillations in the vertical and at the expense of the radiating power of the oscillator, the latter being *cæteris paribus* less for low than for high frequencies. Moreover the spark in the vertical oscillator which normally dissipates an undue amount of the energy of the oscillations, has its resistance enhanced by the reduction of the amplitude of the current oscillations due to the presence of the inductance coil.

This latter difficulty may in a measure be overcome at the expense of any increase of the energy supplied to the oscillator, by shunting the spark gap by a condenser of large capacity. The discharge of the condenser across the spark gap increases the current through the spark and thereby reduces its resistance and damping effect upon the oscillations. The damping effect of the radiation still remains and the persistency is still too much limited for practical purposes.

So far we have considered only the *natural oscillations* of the vertical oscillator which are produced by charging the elevated conductor to a high potential and then permitting it to discharge to earth. When, however, a high degree of persistency, a pure sine wave and a great amplitude of oscillation are desired, the spark gap is removed from the vertical oscillating circuit and a simple harmonic electromotive force is impressed upon the vertical oscillator in its place. The resulting vibrations in the vertical oscillator are then *forced simple harmonic vibrations*. In order that they may be of great amplitude, the frequency of the impressed force is made to correspond to the fundamental of the vertical oscillator or to one of its harmonics, in which cases the reactance of the vertical oscillator is nil.

A simple arrangement for producing forced, simple harmonic vibrations in the vertical oscillator is shown in Fig. 9 in which G is an alternating current generator, k is a key, P shows the connection to the terminals of the primary of a spark coil, S is a spark gap between the terminals of the secondary of the spark coil, C_1 is a condenser, L_1 is an inductance, I_1 and I_2 are the primary and secondary coils of a high-frequency transformer, T is the vertical wire and E is the earth.

There is a variety of ways in which substantially the same result may be accomplished, but there is not space in this paper to consider more than one arrangement.

For the type of elevated conductor which we are here considering, i. e. a cylindrical copper wire of length a and radius r the reactance

of the elevated conductor *per se* is given with a degree of approximation ample for engineering calculations by the expression;—

$$Z = -Lv \cot \frac{na}{v}$$

where $$L = 2 \log_e \frac{4a}{\rho} - k$$

and where $$k = 5{\cdot}584 - 3{\cdot}169\left(\frac{na}{v}\right)^2 - 0{\cdot}3269\left(\frac{na}{v}\right)^4$$ for values of a between 0 and $\frac{\pi v}{2n}$

In these expressions v is the velocity of light and n is the periodicity of the impressed force or $\frac{2\pi}{T}$ where T is the time of a complete oscillation.

The reactance Z therefore vanishes when $n = \frac{2\pi}{T} = m\frac{\pi}{2a}$ where m is an odd integer. The wave lengths corresponding to this condition are therefore $\lambda = VT = \frac{4a}{m}$. The wave-length of the fundamental is therefore 4a and the harmonics are all odd.

For frequencies lower than the fundamental the reactance is negative or a capacity reactance. For frequencies between that of the fundamental and its first harmonic the reactance is positive or an inductance reactance. For frequencies between that of the first even harmonic and the first odd harmonic the reactance is again negative or a capacity reactance. In other words the reactance of the vertical wire measured at the source of disturbance or point of the system is either that of a condenser of capacity $\frac{1}{\quad}$ or of an inductance $\frac{1}{\quad}$ depending upon whether $\cot \frac{na}{v}$ is positive or negative.

The condition for zero reactance in the vertical conductor system is obviously $Z_1 + Z_2 = 0$ where Z_2 is the reactance of the apparatus connected between the vertical wire and the earth. It must therefore be an inductance reactance for frequencies which make the reactance of the vertical wire a capacity reactance and

conversely it must be a capacity reactance for frequencies which make the reactance of the vertical wire an inductance reactance.

The curve shown in Fig. 10 gives the observed apparent capacity of vertical wires 0".08 in diameter varying from 40 to 150 feet in length, when the periodicity of the impressed force is 9.78×10^{5}. In other words it gives the observed apparent capacity of vertical wires for values the angle of $\frac{ns}{v}$ from 0.3976 to 1.790 and for values of the ratio $\frac{4a}{\lambda}$ from 47.520 to 213.800.

The reactance $Z_{"}$ of the apparatus through which the vertical wire is connected to ground may most simply be made negative, when this is necessary, by the insertion of a condenser in series with the coil $L_{"}$, but this result may be accomplished in a variety of ways for the description of which there is not space in this paper.

It will be seen that by making $Z_{"} + Z_{'}$ (or $Z_{"} - Z_{'}$) equal, but opposite in sign to the reactance of the elevated conductor, powerful oscillations of any desired frequency may be developed in the vertical oscillator by means of forced vibrations, whereas when the natural oscillations of the vertical oscillator are resorted to the frequency must necessarily be less than that of the fundamental of the oscillator.

Concerning the arrangement illustrated in Fig. 9, there is much of detail which requires attention in order that the apparatus shall satisfactorily fulfil the requirements of radiating a persistent train of simple harmonic waves. For instance, if a dielectric having considerable electrostatic hysteresis be employed in the condenser, a surprisingly large amount of energy will be dissipated in this dielectric. The magnitude of this loss is due to the fact that the energy dissipated increases both with the potential difference employed at the terminals of the condenser and also with the frequency. Since potential differences developed at the terminals of the condenser amounting to 50,000 volts and oscillations having frequencies of 3,000,000, are not unusual in wireless telegraphy, it is easy to see that the losses in the dielectric of a condenser in a wireless telegraph circuit are of a far greater order than that in the dielectric of condensers employed in the usual power or lighting circuits.

Moreover the specific inductive capacity of most dielectrics is a function of the density of the displacement current in the dielectric, and when such dielectrics are employed in the condenser in an oscillating circuit the resulting oscillations are not simple harmonic in form and are not isochronous throughout the train. in series with the coil $L_{'}$, but this result may be accomplished in

2806

Air condensers should therefore be used in wireless telegraphy to the exclusion of any other type pending the publication of the results of certain investigations which are being conducted with the view of supplying a dielectric of high dielectric strength and constant specific inductive capacity.

The coils used in wireless telegraphy should not have iron cores except the iron be very finely comminuted and imbedded in a non-hygroscopic dielectric matrix. It has even been found by the author that coils wound on a wooden cylinder do not operate satisfactorily when used in the oscillating circuits of wireless telegraphy. The coils for this purpose are best constructed by winding a few turns of bare copper wire in a single layer on a skeleton frame made of ebonite, care being taken to separate the turns by such an amount that the sum of the air spaces between the wires of the turns is equal to or slightly greater than the sparking distance in air corresponding to the greatest potential difference liable to occur at the terminals of the coil when the apparatus is in operation.

If the local oscillating circuit C_1 I_1 L_1 S of the arrangement shown in Fig. 9 were isolated, its oscillations would be expressed by $i = \frac{e}{L} \frac{1}{\sqrt{\frac{1}{LS} - \frac{R^2}{4L^2}}} \cdot e^{-\frac{R}{2L}t} \cdot \sin \sqrt{\frac{1}{LS} - \frac{R^2}{4L^2}}$ where i is the current, e is the potential to which the condenser C_1 is charged at the time when the spark occurs at S, L is the inductance of the circuit, R is the resistance and S is the permittance or electrostatic capacity of the condenser.

If the oscillator is at all persistent $\frac{R^2}{4L^2}$ is negligible compared to $\frac{1}{LS}$, and the expression reduces to

$$i = e \sqrt{\frac{S}{L}} \cdot e^{-\frac{R}{2L}} \cdot \sin \frac{t}{\sqrt{LS}}$$

The time required to fall to $\frac{1}{e}$ th of their initial amplitude is therefore $t = \frac{2L}{R}$

The number of oscillations per unit of time is $\frac{1}{2\pi\sqrt{LS}}$

The measure of the persistency of the circuit is therefore proportional to $\sqrt{\frac{L}{R'S}}$

For a given frequency, $L_n = \frac{I}{Sn}$ so that the persistency for a given frequency is proportional to $\frac{L_n}{R}$, where n is 2π times the frequency.

An isolated circuit of this type may be made to give extremely persistent simple harmonic oscillations, but if it be given a large co-efficient of mutual induction with another oscillator of relatively low persistency, such as the vertical oscillator V_1E of the arrangement shown in Fig. 9, two things happen. In the first place the oscillations of the circuit are in general no longer simple harmonic, but are broken up into two simple harmonic oscillations of different frequencies, and in the second place the persistency is greatly reduced.

To overcome this difficulty it is necessary either to make the magnetic leakage of the high frequency transformer, connecting the local oscillating circuit with the vertical oscillator, unusually large, or else to add to the local oscillating circuit an inductance coil L_1 with sufficient inductance to swamp by its effect the reaction from the secondary circuit.

When intense radiation is desired, it is necessary to make the capacity S of the condenser C_1 in the local oscillating circuit large compared to S' the apparent capacity of the elevated conductor *per se*, for the frequency employed.

Receiver.

Since the electromagnetic waves to be received at a wireless telegraph receiving station are horizontally polarized at the earth's surface, an electrical oscillator whose axis is normal to the earth's surface is employed at the receiving station. This oscillator may either be connected to earth at its lower extremity or it may be connected to a device having reactance equal for all frequencies to the reactance of the vertical oscillator. It is to be remembered in this regard that at the receiving station we are not concerned with what becomes of the energy which is dissipated by the re-radiation of the energy from the receiving vertical oscillator.

We shall consider again a simple concrete case, and shall assume the elevated conductor to be a cylindrical copper wire of length a and radius ρ as in the case of the transmitter, though it must by no means be assumed that the elevated conductor at the receiving station must necessarily be similar to that at the

2808

transmitting station, or, in fact, that it must bear any resemblance to that at the transmitting station except in so far as its axis is preferably normal to the surface of the earth

As in the case of the transmitting station, only one simple arrangement of the apparatus sufficient to give the desired result will here be considered. By this arrangement messages transmitted by means of persistent trains of simple harmonic electromagnetic waves of a predetermined frequency may be received to

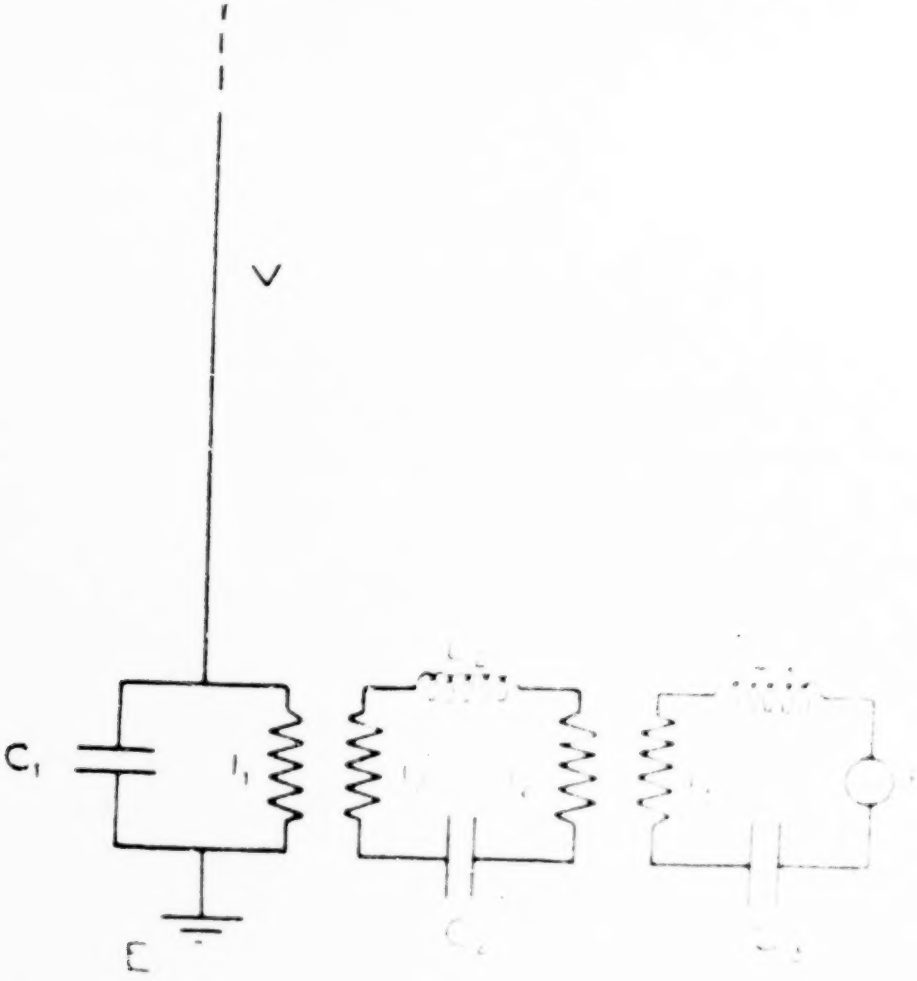

Fig. 1.

the exclusion of messages transmitted in similar ways [illegible] ially different frequencies, and without interference [illegible] waves. Such an arrangement of the [illegible] is shown in the diagram. In this [illegible] device which is indicated at R is [illegible] L, R which is made reasonant to the [illegible] which the station is intended to [illegible]

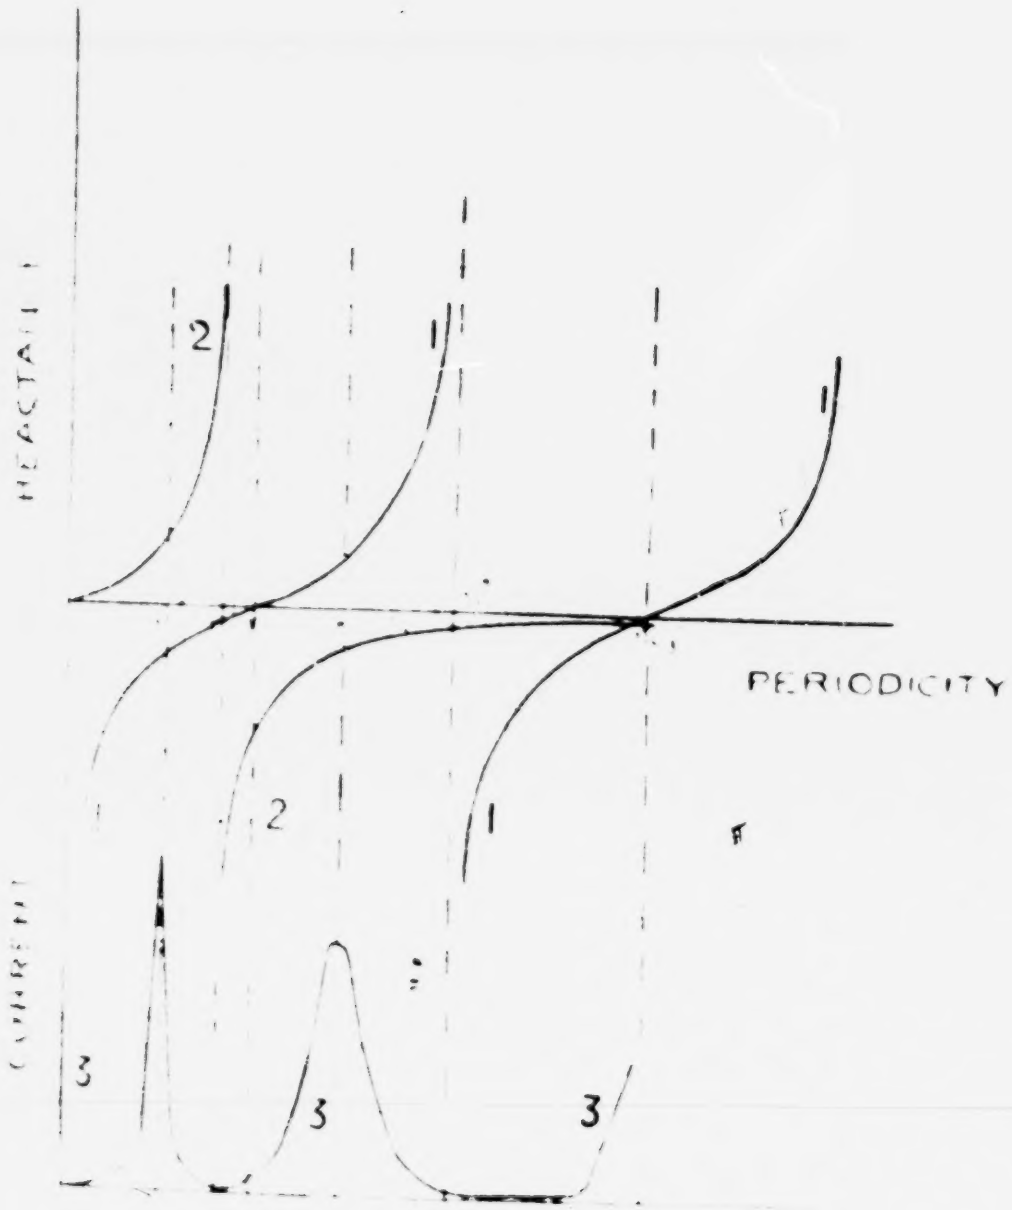

Fig 12

circuit C_2 I_2 L_2 I_2' resonant to the same frequency and called a "weeding-out circuit", is interposed between the first mentioned circuit and the vertical oscillator.

The branch circuit consisting of the coil I_1, and condenser C is not, when taken by itself, resonant to the same frequency as the other local circuits, but is so proportioned that when connected as a branch circuit, forming a part of the vertical oscillator system, the latter shall respond most energetically to persistent trains of waves of that frequency falling upon the vertical wire.

The way in which this is accomplished is perhaps more easily seen by a graphical demonstration than by the use of the analytical solution, though the latter is by no means difficult.

The curves in Fig. 1 illustrate the point in question. Curve 1 represents the reactance of the vertical wire measured at its point of attachment to the loop circuit, for varying periodicities of the impressed force. It will be seen that the periodicity of the fundamental of the vertical wire is at the point n_1'', where the reactance first vanishes. The first even harmonic is at n_2'', and the periodicity of its first odd harmonic is at n_3'', where the reactance again vanishes. Normally therefore curve 3, which is the current curve for varying periodicities of the impressed force on the vertical wire would show maxima at n_1'' and at n_3''. The reactance of the loop circuit for varying periodicities of the impressed force, measured across the points of its attachment to the vertical wire and earth connection is shown in Curve 2. The total reactance of the vertical oscillator measured at the earthed terminal is the algebraic sum of the two reactances shown in Curves 1 and 2, and as a result the current curve 3 shows maxima, not at n_1'' and n_3'', but at periodicities n, n'' and at a periodicity slightly higher than n_3''.

These are the points at which the reactance of the loop circuit is equal, but opposite in sign, to that of the vertical wire.

The periodicity of the local loop circuit *per se* is n; and for this periodicity the current in the vertical wire is practically nil.

The "weeding-out circuit" and the circuit containing the receiver are both resonant to the periodicity n, so that for persistent trains of waves of that periodicity the energy of the oscillations set up in the vertical oscillator is transmitted directly to the receiver, but persistent trains of waves of other frequencies, either produced by slight response in the vertical oscillator or else produced oscillations of the periodicity n'', or of a periodicity slightly higher than n_3'' have little effect on the receiver. To such periodicities the "weeding-out circuit" and the circuit containing the receiver are extremely irresponsive so that the receiv-

ing device receives but an inappreciable amount of the energy of the waves.

In the case of impulsive waves the vertical wire tends to respond only to its own natural rates of vibration as affected by the loop circuit, that is to say, it tends to oscillate at periodicity n'' and to upper harmonics. Such waves acting on the vertical wire, have little tendency to develop oscillations of the natural period of the loop circuit as affected by its connection with the vertical wire, namely n, and the receiver is therefore also protected from the effects of such impulsive waves.

All that has been said regarding the effects of electrostatic and magnetic hysteresis in the description of the transmitting station applies with added force to the apparatus at the receiving station. It is, in fact, much more important to exclude the effects of hysteresis from the receiving circuits than from the transmitting circuits, and it may be laid down as an important rule that under no circumstances shall solid or liquid dielectrics be used in the receiving circuits.

Moreover the injuction in regard to making the mutual inductance small between oscillators at the transmitting station applies in the case of the resonant circuits at the receiving station, since if the mutual energies of the related resonant circuits be not small compared to their self energies, the resonant circuits will modify one another's natural periods and each circuit will respond to more than one periodicity.

Finally it may be said the measure of the selectivity of a resonant circuit is proportional to $\sqrt{\frac{L}{R^2 S}}$, this expression being the same as that found in connection with the persistency of an oscillating circuit. For a given periodicity, therefore, the selectivity is proportional to $\frac{Ln}{R}$

So great is the selectivity of resonant circuits constructed of air condensers and properly designed inductance coils that there is no difficulty in adjusting such circuits to resonance for a given frequency with an error of less than one part in 3,000.

The importance of the "weeding-out circuit" in the receiving station becomes apparent when we observe that the selectivity of the receiving vertical oscillator is greatly diminished by the dissipation of energy, which results from the re-radiation of energy by that oscillator and that the selectivity of the resonant circuit containing the receiver may be greatly diminished by the energy absorbed by the receiver and utilized in its operation.

[fol. 2446] PLAINTIFF'S EXHIBIT NO. 120

IN THE COURT OF CLAIMS OF THE UNITED STATES

MARCONI WIRELESS TELEGRAPH COMPANY, Plaintiff,

vs.

UNITED STATES, Defendant

Copy of Preliminary Report of Interdepartmental Radio Board on Plaintiff's Claim and Accompanying Letter of Oct. 8, 1920. Luella F. Little, Notary Public

INTERDEPARTMENTAL RADIO BOARD,
3341-3343 New Navy Building,
Washington, D. C.

October 8, 1920.

Gentlemen:

There is enclosed herewith draft of preliminary report as to your claim against the United States for compensation for use of your inventions in radio patents. The report is to be understood as involving no waiver or admission on the part of the Government in case a settlement is not reached between it and Claimant. In applying the views expressed in this preliminary report to a review of the radio apparatus purchased or manufactured by the Government, the Board considers that a fair compensation to be allowed in the matter of this claim is $1,063,701.82.

Due steps are being taken to render effective the results arrived at by the Board and the payment of awards finally agreed upon. Meanwhile, an opportunity is offered the Claimant to review the Board's report with a view to reaching agreement between the Board and the Claimant. To this end the Board has set apart Monday the 18th of October, 1920, at 10 A. M., for further discussion of this claim with you and your counsel. Please advise the Board as to whether you will attend on that day. It is pointed out that it has been necessary to set other days of the two weeks beginning 18th October for hearing other claimants, so that it will be difficult to change the date assigned to you, and it

is important, in view of the approaching assembly of Congress, that the matter be disposed of at the time set.

Very respectfully, (signed) E. H. Loftin, Lieutenant-Commander, U. S. N., Chairman.

Marconi Wireless Telegraph Co., Woolworth Bldg., New York City. Copy to Messrs. Sheffield & Betts.

[fol. 2447] CLAIM No. 2

Marconi Wireless Telegraph Co

This claimant is the owner of a large number of patents, a list of which is given in the papers presenting the claim, but pressed its claim only upon the following four patents with the understanding that if a settlement were reached thereon, all claim would be waived as to these other patents:

Re 11,913, Marconi, 609,154 Lodge, 763,772, Marconi, 803,684, Fleming.

Reissue 11,913, to Marconi, granted June 4, 1901, of original patent of Marconi No. 586,193, granted July 13, 1897, on application filed December 7, 1896

This patent expired July 13, 1914. It is the fundamental Marconi patent and has been thoroughly tested by litigation, the result being that while Mr. Marconi's invention was recognized as effecting a most important step in the art, the patent has not been given an effective place by the Courts corresponding to its apparent importance. In the original litigation before Judge Townsend, the first claim of the patent was held to be invalid and it was afterwards cancelled by this claimant. The third claim was held to be valid and to be infringed by the then DeForest structure which included as its detecting element an imperfect contact device operating on the opposite or inverse principle to the Marconi Coherer. The fifth claim involving the use of choke coils was also sustained and held infringed. The claims including the powdered form of the coherer and the provision of an automatic decoherer were held not infringed. The DeForest arrangement, as to the relation between the detector or the spark transmitter and the antenna seems to

have given Judge Townsend no difficulty in this case. (138 Fed. 657, Marconi *v.* DeForest.)

When the patent again came before Judge Townsend (Marconi *v.* American DeForest, 154 Fed. 74) on motion for preliminary injunction, the Court refused an injunction as to DeForest's new apparatus which included a loop radiator and receiver and an electrolytic detector.

When the patent was again tested in the suit before Judge Veeder against National Electric Signaling Co., claim 3 was the only one passed upon and was held to be not infringed on two counts; one, by reason of the removal of the spark producer at the transmitter and the detector at the receiver out of the antenna, and, two, by reason of the employment of a form of detector which was not, in the opinion of Judge Veeder, an imperfect contact such as contemplated by Marconi. Whatever may be the view of the Board as to the Processes whereby Mr. Marconi seems to have been deprived of a result equal to the real scope and value of his invention, the Board does not feel it can go beyond the opinion of Judge Veeder, which has not been modified by any later decision, and as there has been brought to the attention of the Board no instance of a use by the Government which would come in conflict with the [fol. 2448] scope of the claim as defined by Judge Veeder, no allowance can be made on the claim under this patent.

609,154, to Lodge, Granted August 16, 1898, on Application Filed February 1, 1898; Expired August 16, 1915

Reference is made to paper No. 11 in the appendix for the history of the litigation under this patent. Its validity has been uniformly sustained and it is accepted by the Board as the fundamental patent on the use of loading coils in the antenna whether at the transmitter or receiver. A part of the patent which has not been made the subject of claim for infringement but which has been discussed as to its bearing upon the Marconi "four circuit tuning" patent 763,772, is the structure illustrated in Figs 3 and 4 of the Lodge patent and referred to in claim 6. The system here involves, besides the means for synchronizing the radiating circuit, "means for charging it by an aerial disruption or impulsive rush." It is considered that this feature of the Lodge invention is in effect carried out in lesser degree than that specified by Lodge, but still effectively, in those Government stations in which a quenched gap excitation is em-

ployed. (See in this connection opinion of Judge Neterer in Marconi *v.* Kilbourne & Clark, 239 Fed. 328.)

The patent to Lodge, therefore, will be given, in accounting, a weight due both to the synchronizing coils and to the employment of impulse excitation in transmitters employing the quenched gap or other form of impulse excitation, if there be any.

Laches. From the time of grant of this patent, August 16, 1898, or shortly thereafter when radio assumed real proportions, this patent of almost fundamental character was infringed widely and with impunity. The use of loading coils such as contemplated in the patent by the United States Government dates from at least 1902, all without protest on the part of the owners of the patent until after the acquisition of the patent by the Marconi Wireless Telegraph Company of America on March 19, 1912. The defense of Laches which was found good as against this patent by His Honor, Judge Veeder, in Marconi *vs.* National Electric Signaling Co., 213 Fed. 815,863, is applicable with increased force in the case of the United States. The Board is reluctant to apply this rule as to purchases made by the United States after the acquisition of the patent by the Marconi Company and its vigorous and prompt proceeding to protect its rights thereunder, but it is considered by the Board that the rule may be justly applied as against all purchasers made before the acquisition of title by the Marconi Company and which occurred while the then owner of the patent was asleep upon his rights. It is likely that some of these installations purchased before the acquisition of title by the Marconi Company remained in operation after such acquisition of title and that under other conditions the Marconi Company, the claimant here, might be entitled to recover for such use of those installations as occurred while the patent belonged to it. It would, however, be difficult to properly apportion such an award at this late period. The Board is proceeding on a theory of settlement based in all cases on cost price and not extent of use, the use by the Government being for the most part non-commercial and not susceptible of accurate monetary determination. It is thought that full justice will [fol. 2449] be done, recognizing the aversions of the Government to take advantage of a technical defense where it has actually used private property but also bearing in mind the above disabilities, if the award under this patent is limited in all cases to purchases occurring after March 19,

1912, disregarding entirely all installations which may have been made prior to that time whether they remained in use or not.

The Board has not ignored in reaching this view the fact that the patentees' right of injunction is not available against Government infringement and that up till the date of the Act of June 25, 1910, the right of recovery was restricted, but the present claimant delayed its action under that Act for over six years after its passage, the action not having been actually filed in the Court of Claims until over a year after the expiration of the patent. This delay cannot be considered as fully justified by intermediate test cases against other infringers and it is thought that sufficient justice will be done to the claimant by an allowance on the above stated basis.

Stations using dynamos or alternators as radio-frequency generators were not used by the Government prior to the expiration of the Lodge patent and thus do not appear in the accounting thereunder.

763,772, to Marconi, Granted June 28, 1904, on Application Filed November 10, 1900

The history of the litigation under this patent is shown in paper No. 11 of the appendix. It appears to have been uniformly sustained and the Board accepts the patent as having been sufficiently established to cover any wireless system in which at the transmitter effective transfer of energy is obtained between a closed persistent primary circuit and an open non-persistent secondary circuit, with corresponding but reversed arrangement in the receiver. The claims are limited to an open circuit radiator at the transmitter and absorber at the receiver, except claim 2 for the receiver, which, however, has as an element a tuning inductance in the antenna. These specific limitations when taken with the language of the specification, giving an effective meaning to the use of an open circuit as a quick radiator and effective absorber, and with the discussion of Judges Veeder and Neterer would seem to exclude from the accounting to be made by the Government its various loop receiving circuits which cannot come under the term "open circuit" of most of the claims, and which do not include a variable inductance in the antenna as called for by claim 2.

Accounting, however, will be made on all systems having

open antenna whether at the transmitter or receiver coupled with a charging or receiving circuit in such manner that an effective transfer of energy takes place, from one circuit to its coupled circuit by the use of syntony, with modifications expressed below.

Note is taken of the fact that in the litigation heretofore it has not been expressly determined that transmitters employing quenched gaps, and therefore impulse excitation, are included within the terms of the patent. In the case of Marconi *vs.* Kilbourne & Clark, a circuit in which it was argued that there was no effective transfer of energy from the one circuit to the other, the two being substantially energized simultaneously, and in which at any rate there was no effective transfer from one to the other due to [fol. 2450] syntony, was held not to infringe. This, however, is not decisive of the present issue, as to the use of quenched gaps by the Government in which there is a close coupling and a slight or negligible detuning, and in which, undoubtedly, advantage is taken of syntony to secure an effective transfer of energy. The entire period covered by the claim has seen the use of structures of the class at both the transmitter and receiver, and it has taken many forms. The oscillation producer has included open gaps whether stationary or rotary and stationary quenched gaps of various forms. Also alternators of high frequency is current generators have been used in a circuit coupled to the radiating circuit.

A careful study of the various claims of this patent which have been adjudicated and held valid shows claim 10 to be broadest. This claim reads as follows:

"10. A system of wireless telegraphy, in which the transmitting station and the receiving station each contains an oscillating transformer, one circuit of which is an open circuit and the other a closed circuit, the two circuits at each station being in electrical resonance with each other and in electrical resonance with the circuits at the other station, substantially as described."

The language of this claim is on its face, broad enough to include all systems to which there are two circuits either at the transmitter or received and which circuits are in resonance. The only limitation is that one of the circuits must

be an open circuit. The language of this and other claims of the patent is, however, to be construed in the light of the various decisions of the courts and particularly the latest one—the only one going to an appellate court after final hearing—Marconi Wireless Telegraph Co. of America *vs.* Kilbourne & Clark rendered by the Circuit Court of Appeals for the Ninth Circuit.

The Board discusses below whether any of the Government's continuous wave apparatus where tuned coupled circuits are used, come under the patent. The most general exceptions from accounting are the Navy arc transmitters wherein the arc is placed directly in the antenna circuit and the Navy loop receivers in which there are either single circuits or, where a loop is coupled to the secondary, the combination does not include an open circuit.

Accounting will, therefore, be made on all apparatus with the exceptions noted above. But in considering quenched gap transmitters it will be borne in mind that these systems are very closely allied to the impulse excitation systems of Kilbourne & Clark and of Lodge's patent 609,154, and it may be strongly urged that much of the reasoning of the Court of Appeals in the Kilbourne & Clark case would tend to show that these systems are not equivalents of that claimed by Marconi. The specific point is not yet adjudicated, and the patent is not entitled to the weight of an adjudicated patent in this respect.

High Frequency Alternators. The Marconi Company was not understood by the Board to make any claim for compensation for the use of the Lodge and Marconi inventions in these sets, but the Board has of its own motion considered the subject. The question has not been found discussed in any litigation.

In considering the application of the Marconi patent 763,772 to stations having high frequency alternators as a [fol. 2451] source of oscillations, various conditions present themselves. There are three of such stations with which the Government is concerned.

The New Brunswick and Tuckerton stations need no discussion, their temporary use by the Government having been on lease from the claimant—acting in the one case on its own behalf, and in the other case as representative of the foreign owner.

The station at Sayville, Long Island, built by the Atlantic Communication Company, was seized by the Alien Property custodian, either direct or through acquiring the stock of the Company, in April, 1917. At that time the transmitter employed the High Frequency Generator with frequency transformers involved in the defense of Kintner, et al. *vs.* Atlantic Communication Company, 249 Fed. Rep. 73. The property was purchased by the Navy from the Custodian October 11, 1918. Meanwhile the station had been operated by the Navy—but the alternator referred to not having been found efficiently operative, an arc transmitter was put in service about January 1, 1918. It is doubtful whether the Government's mere ownership through the Custodian could under the circumstances be considered an infringement. Furthermore, it is very doubtful whether the system itself infringes on the Marconi patent 763,772. The alternator circuit is so closely coupled to the antenna as to be practically in the antenna. There is no reservoir action and no persistent oscillation of the alternator circuit in the sense of the Marconi patent. The amount of use was small. On the whole, the Board has not felt warranted in conceding any liability on the part of the Government in this case.

Vacuum Tube Transmitters. In the majority of instances, vacuum transmitters employed by the Government have had but a single circuit, the antenna being so connected to the vacuum tube elements that it comprised within itself a part of the oscillating circuit of the vacuum tube generator. In some instances, however, vacuum transmitters have had two circuits, one an oscillating circuit connected to the elements of the vacuum tube and the other an antenna circuit, and where two circuits are so employed, they are in general in tune with each other. The Board is of the opinion, however, that a continuous wave transmitter of this type does not come under the terms of the patent in that no "reservoir action" enters into the principle of exciting the antenna. The oscillations are not damped but continue in constant amplitude and the transfer of energy takes place each cycle without there being any necessity for considering the matter of storing energy in a reservoir circuit to be slowly drawn upon by an antenna or open circuit.

For these reasons the Board is of the opinion that the limited instances of the employment of vacuum tube transmitters having coupled tuned circuits are not cause for accounting under this patent.

893,684, to Fleming, Granted November 7, 1905, on Application Filed April 19, 1905

This is the well-known "Fleming valve patent" which was sustained by Judge Mayer in the suit against the De-Forest Radio Tel. & Tel. Co., 243 Fed. 560. Are further proceedings in this litigation are related in paper No. 11 in the appendix. It may be noted that by the later decisions of Judge Mayer on hearings on supplemental bill, the patent was held to include the DeForest amplifier and oscillion—[fol. 2452] the original decision having held infringement as to the DeForest audion used as a detector. Proceedings are now being had before the master and it has been represented to the Board that an effort is being made by the defendant to exclude from the accounting and take out of the effect of the decision certain types of three-electrode tubes adapted particularly for certain purposes and claimed to operate on a different principle from that on which the tube of the Fleming patent operates.

Basing its action upon the decisions of the Court heretofore rendered, and which go into the matter so fully that it is unnecessary for the Board to express it, the Board will tentatively include in the accounting, subject to any later exclusion therefrom, by the final award in the above suit, of certain types of apparatus, all so-called vacuum tube detectors, amplifiers and oscillions, irrespective of the pressures used.

The Fleming patent includes not merely the tube structure, but the connecting circuits. But the tubes and the circuit are not essentially different from the corresponding parts in the Edison patent 307,031 of October 21, 1884. The novelty claimed lies rather in the application of the invention to radio frequencies than in any particular construction of the tubes or arrangement of the circuits.

The purchases by the Government are largely of tubes independent of the circuit. It is difficult to determine when the tubes were used or in what particular circuits they have been placed. Considering that the use contemplated involved the sooner or later association of the tubes in circuits to constitute the infringing combinations of the patent, the Board has concluded that the award as to these purchases of tubes should be based on their purchase price without undertaking the impossible task of tracing them to the circuits in which they—or some or them—were actually used.

In view of the disclaimer filed by the Claimant on November 17, 1905, tubes in systems employing only low frequency will be omitted from accounting.

[fol. 2453] CLAIMANT'S EXHIBIT NO. 121

IN THE COURT OF CLAIMS OF THE UNITED STATES

MARCONI WIRELESS TELEGRAPH COMPANY, *Plaintiff*.

vs.

UNITED STATES, *Defendant*

Interdepartmental Radio Board's Letter of April 16, 1921
Luella F. Little, *Notary Public*.

Interdepartmental Radio Board

2344 New Navy Building,

Washington, D. C.

April 16, 1921.

Messrs. Sheffield & Betts, 52 William Street, New York, N. Y.

Attention Mr. L. F. H. Betts

SIR:

Claim No. 2—Marconi Wireless Telegraph Co.

Referring to your conference with the Board on Apr. 7 and your further conference with Mr. Knight of the Board on April 13 in the matter of the above claim, the Board has decided that it can not make any change in its method of accounting such that due weight will not be given the Lodge patent after its expiration in 1915. The Board believes its position in this respect is sound and the only one that should be followed.

It is realized, however, that you are not interested in the method of accounting adopted by the Board provided it arrives at a figure which will be acceptable to your clients, but unfortunately the Board can not be governed in its methods by the indifference of claimants as to such methods, but feels that they must be founded on the rules laid down by the courts in patent accountings.

A review of the accounting shows that the weight given by the Board to the Arco-Rendahl patent on quenched gaps, owned by the Government, reduced the allowance to your clients by $194,967.20. The Board is willing to revise its accounting so that this patent is not considered, which additional sum would increase the recommended allowance to your clients to $1,253,389.02.

[fol. 2454] The Board has found that its settlement with others on the contracts in which your clients had warranted the Government amounts to approximately $75,000.00. In other words, this amount should be added to the amount above to arrive at the total value to your clients of this proposed settlement, or $1,328,389.00.

You intimated to Mr. Knight that you are prepared to recommend to the committee of the Marconi Company handling this claim that it accept a figure equivalent to 5 per cent of the cost of apparatus involving some or all of the Marconi Company's patents. You handed to Mr. Knight a sheet showing that you had estimated the cost of apparatus to be $28,425,413.79, and that 5 per cent of this sum is $1,421,270.68. A review of the Board's accounting shows that your estimated cost of apparatus is in error, the actual figure being $26,399,490.60, 5 per cent of which is $1,319,974.53.

It is believed that you arrived at your figure from the data listed on page 3 of your brief of Feb. 2, 1921, when you were heard by the Board. It is pointed out that in the item of "Arc Transmitters", more than two million dollars of this amount involved apparatus purchased after the expiration of the Lodge patent, which amount is practically equivalent to the discrepancy between your figures and the Board's figures.

Reviewing the above, it is pointed out that the Board's herein-proposed recommended allowance plus the saving on warranted contracts is in excess of a 5 per cent allowance on the total cost of apparatus involving the Marconi Company's patents by approximately $9,000.00.

It is suggested that you submit this revised proposed recommendation to the committee of your clients at an early date. If acceptable, the Board's recommendation to the several heads of department will be an award to the Marconi Telegraph Company of $1,253,389.02.

Very respectfully, E. H. Loftin (Signed) Lieut. Commdr., U. S. N., Chairman.

JOHN STONE STONE, OF CAMBRIDGE, MASSACHUSETTS, ASSIGNOR TO WILLIAM W. SWAN, TRUSTEE, OF BROOKLINE, MASSACHUSETTS.

SPACE TELEGRAPHY

SPECIFICATION forming part of Letters Patent No. 767,984, dated August 16, 1904.

Application filed November 25, 1903. Serial No. 182,832. No model.

To all whom it may concern:

Be it known that I, JOHN STONE STONE, a citizen of the United States, and a resident of Cambridge, in the county of Middlesex and State of Massachusetts, have invented a certain new and useful Improvement in Space Telegraphy, of which the following is a specification.

My invention relates to the art of transmitting intelligence from one station to another by means of electromagnetic waves without the use of wires to guide the waves to their destination, and it relates more particularly to the system of such transmission in which electromagnetic waves are developed by producing electric vibrations in an elevated conductor, preferably vertically elevated.

In my Letters Patent Nos. 714,756 and 714,831, dated December 2, 1902, and in other Letters Patent I have described systems of space telegraphy in which electromagnetic waves substantially simple harmonic in form are transmitted by creating substantially simple harmonic vibrations or oscillations in a sonorous circuit or system of circuits and impressing such vibrations or oscillations upon an elevated conductor. In order that the electric vibrations so impressed upon the elevated conductor, and consequently the electromagnetic waves radiated therefrom, may be simple harmonic in form, I have employed means whereby the individual circuits of a complex of interrelated circuits are made capable of vibrating as circuits of a single degree of freedom. In my Letters Patent Nos. 714,756 and 714,831, and in my Reissued Letters Patent No. 12,149, reissued August 25, 1903, I have described and broadly claimed means whereby such complex of interrelated circuits may be reduced to the equivalent of a number of circuits having a single degree of freedom. I have also specifically claimed therein one of the means whereby this result may be accomplished. The means broadly described and claimed consist in providing each circuit with sufficient auxiliary inductance to render the mutual inductance between it and an associated circuit small compared to the square root of the product of the inductances of the circuits. The specific means therein claimed was an auxiliary inductance-coil in each circuit, whereby the mutual inductance between said circuit and an associated circuit is rendered small compared to the square root of the product of the inductances of the two circuits. Another specific means whereby the same result is accomplished is fully set forth by me in my Letters Patent Nos. 714,832 and 714,833, dated December 2, 1902, wherein I have shown that the function of the auxiliary inductance-coil may be performed by the primary of the transformer connecting the sonorous circuit with the elevated conductor by so proportioning said primary that it shall supply the auxiliary inductance, which in the other specific form of my invention was supplied by means of the auxiliary inductance-coil. This is accomplished by so designing the transformer that the ratio $\frac{M^2_{12}}{L_1 L_2}$ is small compared to unity, which is the opposite course from that in general pursued in constructing a step-up transformer, and is only resorted to in the construction of the so-called "constant-current" transformers, and it may also be accomplished in a plurality of ways set forth in my Letters Patent Nos. 717,467 and 717,515 in the art of wire telegraphy.

In the present specification I confine myself and limit my claims to one of these means, namely, that of so designing the transformer connecting two associated circuits that the ratio $\frac{M^2_{12}}{L_1 L_2}$ is purposely made small compared to unity. In other words, the means herein claimed whereby the complex of circuits is reduced to the equivalent of a system of circuits each of a single degree of freedom is different from that previously claimed by me in that the ratio $\frac{M^2_{12}}{L_1 L_2}$ is made small compared to unity by making the transformer a constant-current transformer, whereas in the other patents I have claimed means for rendering this ratio small compared to unity consisting of auxiliary inductance-coils. In this case the circuits at the transmitting-station

the closed sonorous circuit or closed oscillator, which is a persistently oscillating poor-radiating circuit, and an elevated transmitting-conductor or linear oscillator, which is a good radiating circuit, and therefore a poor oscillator. At the receiving-station the circuits are an elevated receiving-conductor or linear oscillator, which is a good absorbing-circuit and a poor oscillator, and a closed resonant circuit, which is a persistently oscillating circuit, and therefore a poor absorbing-circuit, except for the energy of currents of the frequency to which it is attuned. The particular means employed for reducing the aforesaid system of interrelated circuits to the equivalent of a system of circuits each having a single degree of freedom is a transformer designed as aforesaid, so that the ratio $\frac{M}{L\ L'}$ is made small compared to unity, so that the transformer will have sufficient magnetic leakage to effect the desired result.

In my Letters Patent Nos. 717,467 and 717,545 in the art of wire telegraphy I have described and claimed several specific means of reducing a complex of circuits to the equivalent of a system of circuits each of a single degree of freedom. The underlying principle for accomplishing this result is in all instances that the mutual energy of each circuit with all of the interrelated circuits of the system shall be small compared with the self-energy of said circuit.

The relation of the specific invention herein to be claimed to the broad principle hereinbefore stated may be best understood by having reference to the drawings which accompany and form a part of the present specification.

In the drawings, Figure 1, 3, and 5 represent in diagram apparatus and arrangements of circuits constituting transmitting systems. Figs. 2, 4, and 6 represent in diagram apparatus and arrangements of circuits constituting receiving systems.

In the figures: V is an elevated conductor. M M are transformers. L L L' are inductances. C C C C' are condensers. L_1 L_2 are respectively the primary and secondary windings of the transformer M. s is a spark-gap. A is an alternating-current generator or other source of periodically-varying electromotive force. B is a battery. R is a relay. K is a receiver, herein illustrated as a coherer. k is a key.

In the system illustrated in Figs. 1 and 2 the sonorous circuit s C L and the resonant circuit C C L are each associated with an elevated conductor V by means of a transformer M with magnetic leakage—that is, a transformer in which the primary and secondary windings L and L have such spatial interrelation as to so reduce the mutual inductance between the associated circuits that the ratio $\frac{M'_{12}}{L_1 L_2}$ is small compared to unity, where L L represent the self-inductances of the associated circuits and M the mutual inductance between said circuits. It will be found that when the primary L is in close inductive relation with the secondary L and is then separated therefrom the amplitude of the oscillations developed in said secondary gradually rises to a maximum and that at this point any further separation of the transformer-windings will have the effect of decreasing this amplitude.

The operation of the apparatus shown in Fig. 1 is the same as that of the apparatus shown in Fig. 5 of my hereinbefore-mentioned patent, No. 714,756, and reference may also be had to the description of the operation of the apparatus shown in the figure of my Letters Patent No. 714,832, the function of the auxiliary inductance-coil (designated by the letter L shown in those drawings) being performed by the primary coil L_1 of Fig. 1 of the present case. Similarly the operation of the apparatus shown in Fig. 2 is the same as that of the apparatus shown in Fig. 6 of my Letters Patent No. 714,756, the function of the auxiliary inductance-coil (designated by the letter L in that drawing) being performed by the secondary coil L_2 of Fig. 2 of the present case.

In Fig. 3 the elevated conductor is conductively associated with a sonorous circuit s C L L. In order to impress a simple harmonic electromotive force upon the elevated conductor V, electrical oscillations are produced in the sonorous circuit. These give rise to a corresponding difference of potential at the terminals of the inductance-coil L' in the elevated-conductor system V L' E, and corresponding forced simple harmonic electric vibrations result therein. The inductance of the coil L' being small compared to that of the coil L the oscillations in the sonorous circuit are not materially affected by the association of this circuit with the elevated-conductor system.

In Fig. 4 the elevated conductor is conductively associated with a resonant circuit C L L'. When simple harmonic electric oscillations are set up in the elevated conductor, a corresponding difference of potential is set up at the terminals of the inductance-coil L', and corresponding forced simple harmonic electric vibrations result in the resonant circuit. If the frequency of these vibrations is the same as that to which the resonant circuit is attuned, said resonant circuit responds energetically and has electrical oscillations of relatively great amplitude developed in it, whereas if the frequency of these vibrations be different from that to which the resonant circuit is attuned the resonant circuit responds but feebly and has electric vibrations of relatively small amplitude developed in it. The inductance of the coil L' being small compared to that of the coil L the oscillations in the resonant cir-

but are not materially affected by the association of this circuit with the elevated conductor.

In Fig. 5 the elevated conductor is again conductively connected to a sonorous circuit s C L. In order to impress a simple harmonic electromotive force upon the elevated conductor V, electrical oscillations are produced in the sonorous circuit. These give rise to a corresponding difference of potential at the terminals of the condenser C'' in the elevated-conductor system V C'' L' E and corresponding forced simple harmonic electric oscillations result therein. The capacity of the condenser C being large compared to that of the condenser C', the oscillations in the sonorous circuit are not materially affected by the association of this circuit with the elevated-conductor system.

In Fig. 6 the elevated conductor is conductively associated with a resonant circuit C' L C'. When simple harmonic electric oscillations are set up in the elevated conductor, a corresponding difference of potential is set up at the terminals of the condenser C'' and corresponding forced simple harmonic electrical vibrations result in the resonant circuit. If the frequency of these vibrations is the same as that to which the resonant circuit is attuned, said resonant circuit responds energetically and has electrical oscillations of relatively great amplitude developed in it, whereas if the frequency of these vibrations be different from that to which the resonant circuit is attuned the resonant circuit responds but feebly an has electric oscillations of relatively small amplitude developed in it. The capacity of the condenser C'' being great compared to that of the condenser C', the oscillations in the resonant circuit are not materially affected by the association of this circuit with the elevated conductor.

No mention has heretofore been made of the function of the condensers C''', as these condensers are not essential to the tuning of the circuits in which they are placed, but merely serve to shunt the relays R out of the resonant circuits. In order that these condensers may not appreciably affect the tuning of the circuits in which they are included, and thereby lower the resonant rise of potential at the plates of the condenser C, they are so constructed as to have large capacities compared to the capacities of the condenser C'.

No mention has heretofore been made of the function of the condensers C' and inductance-coils L', as the functions of these elements have been fully described in my applications Serial Nos. 193,371 and 193,372, filed February 13, 1904, and as they form no essential part of the present invention.

I claim—

1. In a system of space telegraphy, an elevated transmitting-conductor serially connected with one winding of a transformer and a sonorous circuit including the other winding of said transformer, said windings being so spatially interrelated as to reduce the complex of interrelated circuits to the equivalent of a system of circuits each having a single degree of freedom.

2. In a system of space telegraphy, an elevated receiving-conductor serially connected with one winding of a transformer, and a resonant circuit including the other winding of said transformer, said windings being so spatially interrelated as to reduce the complex of interrelated circuits to the equivalent of a system of circuits each having a single degree of freedom.

3. In a system of space telegraphy, an elevated conductor serially connected with one winding of a transformer and a persistently-oscillating circuit including the other winding of said transformer, the separation of said windings being sufficient to reduce the complex of interrelated circuits to the equivalent of a system of circuits each having a single degree of freedom.

4. In a system of space telegraphy, a transmitting system comprising a sonorous circuit inductively associated with an elevated conductor by means of a transformer, in combination with a receiving system comprising a resonant circuit attuned to the frequency of the electric oscillations developed in said sonorous circuit and inductively associated with an elevated conductor by means of a transformer, the windings of each of said transformers being so spatially interrelated as to reduce the complex of interrelated circuits constituting the transmitting and receiving systems each to the equivalent of a system of circuits having a single degree of freedom.

5. In a system of space telegraphy, a good oscillator connected with a good radiator or absorber by means of a transformer having sufficient magnetic leakage to reduce the complex of circuits to the equivalent of a system of circuits each having a single degree of freedom.

6. In a system of space telegraphy, a persistently-oscillating circuit, a good radiating or absorbing circuit, and a transformer inductively associating said circuits, the mutual inductance between the windings of said transformer being sufficiently small to reduce the complex of interrelated circuits to the equivalent of a system of circuits each having a single degree of freedom.

7. In a system of space telegraphy, a persistently-oscillating circuit, a good radiating or absorbing circuit, and means for so associating said circuits that the mutual energy of each circuit with its interrelated circuit is rendered small compared with the self-energy of each circuit.

8. In a system of space telegraphy, a persistently-oscillating circuit, a good radiating or absorbing circuit, and means for so in-

ductively associating said circuits that the mutual energy of each circuit with its interrelated circuit is made small compared with the self-energy of each circuit.

9. In a system of space telegraphy, a persistently-oscillating circuit, a good radiating or absorbing circuit, and means for so associating said circuits that the complex of interrelated circuits is reduced to the equivalent of a system of circuits each having a single degree of freedom without the interposition of auxiliary means.

10. In a system of space telegraphy, a persistently-oscillating circuit, a good radiating or absorbing circuit, and means for so inductively associating said circuits that the complex of interrelated circuits is reduced to the equivalent of a system of circuits each having a single degree of freedom without the interposition of auxiliary means.

In testimony whereof I have hereunto subscribed my name this 24th day of November, 1903.

JOHN STONE STONE.

Witnesses:
G. A. HIGGINS,
BRAINERD T. JUDKINS.

Correction in Letters Patent No. 767,984.

It is hereby certified that in Letters Patent No. 767,984, granted August 16, 1904, upon the application of John Stone Stone, of Cambridge, Massachusetts, for an improvement in "Space Telegraphy," an error appears in the printed specification requiring correction, as follows: On page 2, line 66, the symbol "L^1" should read L; and that the said Letters Patent should be read with this correction therein that the same may conform to the record of the case in the Patent Office.

Signed and sealed this 11th day of July, A. D., 1905.

[SEAL.]

F. I. ALLEN,
Commissioner of Patents.

[fols. 2461-2462] PLAINTIFF'S EXHIBIT 122

RADIO PATENTS

Settlement Of Claims Against Government For Use Of Radio Patents During The World War

Hearings

Before The

Committee On Military Affairs

House Of Representatives

Sixty-Seventh Congress, First Session

Monday, May 23, 1921

Statements of

Commander Stanford C. Hooper, U. S. N.

Lieut. Commander Edward H. Loftin, U. S. N.

Capt. Guy Hill, U. S. A.

Mr. Harry E. Knight, Department of Justice.

Mr. Edward G. Curtis, Special Assistant to the Attorney General.

[fol. 2463] Radio Patents

Committee on Military Affairs,
House of Representatives,
Monday, May 23, 1921.

The committee met at 10:30 o'clock a. m., Hon. Julius Kahn (chairman) presiding.

The Chairman. I have called this meeting of the committee this morning to consider a letter which I received, through the Speaker, from the Secretaries of War and Navy and the Attorney General of the United States regarding the settlement for patents which the Government used during the war for the benefit of the country. They have suggested a bill for that purpose, to which I have made a slight amendment. I will ask the clerk of the committee to read the letter.

(The clerk read the letter, as follows:)

Departments of War, Justice, and Navy,
Washington, D. C., May 14, 1921.

DEAR MR. GILLETT: We have the honor to invite attention to the situation that exists as a result of the use by the Government of patented inventions relating to radio communication and the development in that art.

Prior to the war with Germany the Government, principally the War and Navy Departments, found it necessary, because the validity of many patents relating to wireless telegraphy had not been judicially determined, to use wireless apparatus of various kinds without strict regard to the rights claimed by patentees, and during the war both departments used any and all apparatus, principles, and methods of known value without consideration of questions of infringement or proprietorship, giving where necessary its warranty to contractors to protect them from litigation for infringement.

The development of this art has been very rapid and the patent situation with respect thereto is exceedingly complicated. There are many patents relating to the subject and a large number of claims for compensation for alleged use and infringement of patented inventions, among which there is much conflict, have been filed with the War and Navy Departments.

Realizing that the use by the Government had infringed the rights of many patentees, while some of the claims possess little or no merit, and that a fair and reasonable determination of the whole matter would be difficult, long drawn out, and expensive to the Government as well as to the claimants if an adjustment were not arrived at by a reasonable and businesslike consideration of the interests of all parties concerned, a board designated "Interdepartmental Radio Board" was appointed by ourselves consisting of experts from the War Department, Department of Justice, and the Navy Department to consider all such claims, each with reference to its own merits and the merits of all the others. Such board has been considering the matter for nearly three years, giving all questions connected therewith careful, intelligent, and exhaustive consideration.

The claims presented to the board totaled many millions of dollars. Out of the 24 claims brought only 7 stated the amount of the compensation desired, and the total of those 7 was $14,860,000, the rest aggregating probably a much larger sum.

The board, giving due weight to matters of infringement, validity of patents, values of inventions, the circumstances of use by the Government, and the entire value of up-to-date wireless apparatus as the product of all inventions [fol. 2464] combined, has determined a sum of money that the Government should fairly and reasonably pay to the different patentees in proportion to the value of their respective inventions. Such sum will not exceed $2,500,000, which is only a small percentage of the aggregate sum claimed.

The owners of the various patents affected have been informed of the board's determination, and many or all of them have signified a willingness to accept the amounts allotted to them. The work of the board has been most painstaking and careful, and its conclusions and determinations reflect great credit upon its members. If settlement with the various patentees can be effected on the basis of the board's determination, a situation fraught with troublesome consequences would be disposed of to the great advantage of the Government and to the ultimate satisfaction of the claimants, and it is highly desirable, therefore, that provision be made for such settlements.

Therefore it is urgently recommended that the War, Justice, and Navy Departments be empowered to adjust and pay said claims on the basis of said board's determination.

Transmitted herewith is a draft of a provision that it is believed covers the matter adequately, and is suggested as an amendment to the act entitled "An act to provide relief in cases of contracts connected with the prosecution of the war, and for other purposes," approved February 2, 1919, commonly known as the Dent Act.

If at an early date payment could be tendered to all the claimants of the respective amounts found in their favor by said board, it is believed that all claimants having claims of substantial merit would accept settlement and release the Government, and it is earnestly requested that this

matter be given favorable and prompt consideration by Congress.

Very sincerely, John W. Weeks, *Secretary of War.* H. M. Daugherty, *Attorney General.* Edwin Denby, *Secretary of the Navy.*

Hon. Frederick H. Gillett, *Speaker of the House of Representatives.*

(The bill above referred to is as follows:)

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That the act entitled "An act to provide relief in cases of contracts connected with the prosecution of the war, and for other purposes," approved February 2, 1919, and the same is hereby amended by adding thereto the following section:

"SEC. 6. That the Secretary of War, the Attorney General, and the Secretary of the Navy, acting jointly or severally, as in their judgment the circumstances of each case may require, are hereby authorized to adjust, pay, and discharge any and all claims against the United States for or on account of the use or manufacture by or for the United States of any patented invention relating to radio communication in cases in which such patented invention was used without agreement with the owner as to compensation therefor, such settlement of claims to cover both past whether prior to, during, or after the war) and future use where practicable in all cases, and to be based on the determination by such agency as the said Secretaries and Attorney General have designated or established or may designate or establish of all questions of infringement, validity of patents, and value of inventions: *Provided*, That this provision shall not be so construed as to deprive owners of patents who shall not accept settlement under this act of any rights of action conferred by the acts for protection of the owners of patents, approved June 25, 1910, and July 1, 1918, respectively, and for the payment of such claims the sum of $2,500,000, or so much thereof as may be necessary, is hereby appropriated out of any money in the Treasury not otherwise appropriated."

The CHAIRMAN: I have asked the officers representing these three departments to come before the committee this morning for the purpose of explaining the matter to us. I

understand that officers representing the Navy Department will make the opening statements, and we will be very glad to hear them.

[fol. 2465] Statement of Commander Stanford C. Hooper, Officer in Charge, Radio Division, Bureau of Engineering, Navy Department

Commander Hooper: Mr. Chairman, the application of radio-telegraphy for practical purposes is but 20 years old. It is highly scientific, most intricate, and because it is the only practicable means of communication where land wires are not possible, it is most valuable for military purposes. Its growth in these 20 years has been marvelous, of such rapidity that if the military services were to make quick application of the various developments in order to keep abreast of competing nations, there was no time, with the limited skilled force available both in the military branches of the Navy and the Patent Office, to pay proper attention to the patent side of the art.

Today approximately one-tenth of the cable business of the world is being handled by radio. Great improvements in signaling the fleets has been made so that flag commanders are able to give an order on the bridge of the flagship to cause their fleets to turn right and left or about, almost instantly by radio signaling. Prior to this application, maneuvering by flag signaling was slow and uncertain, due to smoke and distance obscuring the flags. Similarly an airplane flight commander is able to telephone by radio his orders for maneuvering his squadrons of airplanes. By virtue of radio the heads of departments on shore are able to give orders to the fleets and individual ships in any part of the world by our wireless system at great increase of efficiency and great saving of cable tolls. Admirals at sea are able to spread their scouts out at great distances apart, keeping in touch by radio, whereas formerly they must cruise in limited areas in order to sight each other and make reports at definite time intervals. This decreases the number of ships required for scouting. The spotting of fleets and of shore batteries has been increased in efficiency hundreds of per cent due to spotting by aircraft which locates the fall of shots with great accuracy due to better observation methods, which would be impossible were it not for the radio with which to communicate the fall of shots.

By means of radio compass instruments, or radio direction finders, it is possible to get an accurate bearing of any ship or station which is transmitting by radio. The Navy has installed for naval ships and for mercantile ships in addition some 70 radio lighthouses on the Atlantic, Gulf, and Pacific coasts, by means of which ships at sea are able to merely call up these stations, and within five minutes be given accurate positions of their locations. This is of greatest assistance to navigation in rainy or foggy weather and the saving of many ships from grounding, and expediting others in reaching a port, whereas, due to fog, etc., they might be delayed for days. Similarly aircraft are aided in reaching their landing fields, where in foggy weather this might be impossible without great risk. The Navy is handling about 60,000,000 words a year in radio traffic. Last year the amount of tolls saved to the Government by means of the Naval Communication Service was in the neighborhood of $7,000,000.

This summary is merely for the purpose of showing that the application of radio is bringing the Government great value in a financial way, as compared to expenditures made for this service.

[fol. 2466] To date there has been no radio company which has reaped great profit from its patents, through which these various developments have been made. In fact, practically all the profits have gone into new developments and new construction, and most of these profits have been purely manufacturing profits.

Two or three times before the war efforts were made to commence the clarification of the complicated radio patent situation in order that royalties should be arranged for to the various companies which owned radio patents. Each time has brought down to the Government department an avalanche of inventors with so many overlapping patents that it was found impossible to determine just who owned the different patents and what the royalties should be. There was no personnel in any Government department capable of handling this matter.

The war came on, and it was universally agreed among the radio companies that they would put aside patent matters until the war was over and give the Government free hand to proceed as best it could to purchase apparatus. This the Government did and with the good will and cooperation of all.

After the war, conferences were arranged between the various departments of the Government interested, principally the War, Navy, and Justice Departments, to discuss methods whereby remuneration might be given those who were justly entitled to royalties on radio apparatus purchased by the Government. The ultimate result was the forming of an interdepartmental radio board, which has for two years constantly been in session with a view to adjusting this matter.

The general policy which governed the board was, first, justice to all concerned; second, the desire to increase incentive to inventions and advance the Government's position in the art of radio telegraph; third, economy for the Government; and fourth, an arrangement for prompt recompensation to all parties.

A list of radio patents purchased by the Government has been compiled, and a list of radio apparatus purchased has been compiled, and the board has worked out a plan to reimburse inventors. In all there are about 500 patents, and that number has been reduced to about 27. That has been accomplished through negotiations with the claimants, and the value of the claims has been reduced to about $2,500,000.

Lieut. Commander Loftin, who has been the head of the board, can give you full information in reference to the board and its method of arriving at its recommendations.

The Chairman: We would be glad to hear the lieutenant commander.

Statement of Lieut. Commander Edward H. Loftin, assistant to the Officer in Charge of the Radio Division, Bureau of Engineering, Navy Department, in Charge of the Patent and Research Sections, with Additional Duty as a Member of the Interdepartmental Radio Board.

Commander Loftin: Mr. Chairman and gentlemen of the committee, I think the first matter I will call to your attention is the authority under which the Interdepartmental Radio Board has been acting, and we have that in the form [fol. 2467] of a precept from the Secretary of War, the Attorney General, and the Secretary of the Navy.

The Chairman: When was that issue?

Commander Loftin: This precept was not issued until February 12, 1921. The reason for that was that that board was informally brought together by orders from the heads

of each of the departments to its own representatives, ordering them to meet with such a board. In our proceedings we found that the situation was quite embarrassing in that we often had inquiries from various claimants as to what our authority was, and what authority we were going to show when we reached our conclusions for having acted as such a board. So we then reported to the several heads of the departments our embarrassment and asked them to give us a formal precept.

Mr. Morin: When were the members of the board originally brought together?

Commander Loftin: The members of the board were originally brought together in August, 1918. Nothing was acted upon until February, 1919. The officers who were originally made members of that board all had duties in the departments. It was during the period of the war, and it was practically impossible for them to undertake the consideration of a situation such as this was.

The Chairman: You mean that the officers representing the Navy all had duties under the Navy Department?

Commander Loftin: Yes, sir; and the officers representing the War Department all had duties under the War Department.

The Chairman: What about the representatives of the Department of Justice?

Commander Loftin: At that time there was only one attorney in the Department of Justice handling patent matters. There were many suits pending against the United States, and he was thoroughly occupied at that time.

Mr. Morin: Has not this board been conducting its business with the approval of the three members of the Cabinet, heads of these three departments, War, Justice, and Navy.

Commander Loftin: Yes, sir; this request was signed by the three members of the Cabinet representing these three departments. The precept says:

Whereas the operations of the War Department and the Navy Department during the war, relating to the furnishing of adequate supplies for radio communication, developed the fact that the patent rights of greatly needed supplies were diversely held, which rendered quantity production by the employment of all the available manufacturing facilities difficult, which situation made obvious the neces-

sity for proceeding with production, without regard to the existence of patent rights, orders for which procedure were issued by both departments, wherein the United States Government directly assumed responsibility for the proper compensation for the unauthorized use of patent rights; and

Whereas large claims were presented to the United States flowing out of such procedure, in addition to others which already had accumulated, and for which suits had been filed against the United States in the Court of Claims; and

Whereas the situation thus produced made obvious the advisability of creating a board of experts in patent law and radio science for the purpose of determining scientifically the measure of liability in which the Government became involved; and

Whereas the Secretary of War suggested the creation of such a board to the Secretary of the Navy and the Attorney General, in which suggestions they concurred, and out of [fol. 2468] which was created by separate appointment representatives of the Secretary of War, the Secretary of the Navy, and the Attorney General, to constitute the Interdepartmental Radio Board, which board has been heretofore organized and has made considerable progress in the discharge of the duties the problems presented seemed to require

Now, therefore, it is directed that the officers and representatives of the several departments heretofore appointed, to wit: Commander Stanford C. Hooper, United States Navy, and Lieut. Commander Edward H. Loftin, United States Navy, representing the Navy Department; Capt. Guy Hill, United States Army, and Robert H. Young, Esq., representing the War Department; Harry E. Knight, Esq., representing the Department of Justice; and any successors of any of said members who shall hereafter be from time to time appointed shall continue as a board, designated the Interdepartmental Radio Board, to investigate, hear, and examine the questions relating to the liability involved in the use by the Government of patents on radio apparatus and similar devices and render to the several heads of the departments mentioned their conclusions and recommendations therein.

Such assistance and information as the board may require will be rendered to it by the officers of the respective departments familiar with patent and technical matters involved in those departments.

Newton D. Baker, *Secretary of War.* Josephus Daniels, *Secretary of the Navy.* A. Mitchell Palmer, *Attorney General.*

To Interdepartmental Radio Board, *Navy Building, Washington, D. C.*

Washington, D. C., *Febraury 12, 1921.*

The Chairman: As I understand it, from the reading of that precept, the Government practically asked these inventors to allow the Government to use their patents, they ultimately to look to the Government for pay for these inventions. That was the purpose of this precept, was it not?

Commander Loftin: Of this order?

The Chairman: Yes.

Commander Loftin: The negotiations were really instigated by several of the main patent holders. During the war we insisted that in all litigation in reference to these patents that the Government was interested and litigation should cease. A number of letters were written to the district courts practically saying that the Government would not tolerate the continuance of litigation on radio patents during the war, and a number of those cases were—in fact, in three cases in which we took such action the cases were set over. The real purpose of that was this: Litigation requires the attention of the engineers of the companies. We had taken a number of the engineers into both services for war purposes, and those who remained with their companies were urgently needed in the production and development of radio apparatus for use during the war.

The Chairman: Was that notice to the inventors in writing?

Commander Loftin: It was to the courts; I am not certain about that; I think we can produce some letters to the companies.

The Chairman: Will you kindly do that and put them in the hearing for the benefit of the members of the committee?

Commander Loftin: I will do that, sir.

[fol. 2469] (The letters referred to are as follows:)

Interdepartmental Radio Board,
Washington, D. C., May 25, 1921.

Hon. Julius Kahn, *Chairman Committee on Military Affairs, House of Representatives, Washington, D. C.*

SIR: Referring to my hearing before the committee on May 23 in connection with the proposed amendment to the Dent Act for the settlement of claims against the Government under patents in the art of radio communication, I am inclosing copies of a number of Navy Department letters which show the department's policy in the matter of suspending litigation on radio patents during the war. This is done in accordance with your request after my reference during the hearing to this particular policy.

Very respectfully,

Edward H. Loftin, *Lieutenant Commander, United States Navy, Chairman.*

January 18, 1918.

GENTLEMEN: From information received by the department from the Bureau of Steam Engineering, it appears that the Government's interests are indirectly involved in the suit of the New York Patents Exploitation Co. against the Mallory Steamship Co., on account of alleged infringement of the Seibt patent, No. 1216615, relating to quenched spark radio apparatus, and that certain information of record in the department or within the knowledge of experts in the department's employ will be of considerable value in connection with the trial of said cause.

In view of the demands made on the entire force of the department's employees under existing conditions, it is not possible that the Government's interests, as affected by said suit, can be given the attention requisite to a proper disposition of the matters in issue, and, as the department's interests will be affected by the outcome of the case analogously with those of the defendant, it is requested that you,

in the public interests, ask the court to stay all proceedings for the duration of the war.

Very respectfully,
Franklin D. Roosevelt, *Assistant Secretary.*

Messrs. Sheffield & Betts, *Counselors at Law, 52 William Street, New York City, N. Y., Attorneys for Mallory Steamship Co.*

April 27, 1918.

Gentlemen: The bureau has received information that you are pushing the suits against E. J. Simon and the Kilbourne & Clark Co. It is believed to be in the interests of the Government to have this litigation stopped.

Please inform the bureau what arrangements you propose to make.

Very respectfully,
H. P. Le Clair, (By direction Chief of Bureau.)

Marconi Wireless Telegraph Co., *Woolworth Building, New York, N. Y.*

December 14, 1917.

Attention of Mr. E. J. Nally.

Gentlemen: The bureau has received information that the patent suit pending against the Government is being pushed by the Marconi Co. You are undoubtedly aware of the fact that in order to defend itself properly, many of the radio experts now with the Government would be required as witnesses for the defense. In view of the fact that we are now prosecuting a war which requires constant attention of all the Navy's experts, it would be impossible for them to take time away from their other important [fol. 2470] work to testify in this case. Thus an injustice would be worked the Government. It is hoped therefore, that the Marconi Co. will be able to see its way clear to a postponement of this suit until after the present war.

Very respectfully,

R. S. Griffin, *Engineer in Chief, United States Navy, Chief of Bureau.*

Marconi Wireless Telegraph Co., *Woolworth Building, New York, N. Y.*

April 7, 1917.

From: Bureau of Steam Engineering.

To: Solicitor.

Subject: Suspension of patent suits during war.

1. There are a number of radio patent suits now in the courts and in prospect which the department is either directly or actively interested in, the principal one being a suit by the Marconi Wireless Telegraph Co. filed in the Court of Claims against the Government. It is impracticable under present conditions, owing to the rush of work, for the bureau to devote any attention to these matters of litigation without taking the attention of the experts from the efficient conduct of its duties in providing and supplying radio sets to the fleets. It is therefore recommended that suitable arrangements be made whereby all litigation of the nature described above be suspended until after the war.

Griffin.

July 11, 1918.

SIR: From information received by the department from the Bureau of Steam Engineering it appears that the Government's interests are involved in the suits of Samuel M. Kintner and Halsey M. Barrett against the Atlantic Communication Co. on the reissue patent No. 12168 and patents Nos. 1050441 and 1053728, relating to the so called heterodyne and sustained wave, now pending before Judge E. Henry Lacombe as master, and that it may be found advisable for the department to intervene and to furnish information and testimony in said matter.

In view of the demands made on the entire force of the department's employees under existing conditions, it is not possible that the Government's interests as affected by said suit can be given the attention requisite to a proper disposition of the matters in issue, and as the department's interests may be affected by the outcome of the case, it is requested that you, in the public interest, ask the court to stay all proceedings for the duration of the war.

W. S. Benson, *Acting Secretary of the Navy.*

Mr. Dean S. Edmonds, *35 Nassau Street, New York, N. Y.*

August 23, 1918.

SIR: Replying to your letter of July 30, 1918, on the subject of the suit between the American Telephone & Telegraph Co. and Mr. Peter Cooper Hewitt.

The suit is apparently not a patent infringement suit and probably does not directly involve wireless. It is further appreciated that you would not under any circumstances press a suit that might embarrass the Government to the slightest degree in the prosecution of the war.

In view, however, of the far-reaching effect of a decision unfavorable to the American Telephone & Telegraph Co. and the importance which they would naturally attach to a proper defense of the suit this bureau is of the opinion that it would be necessary to call upon experts who are now employed on important war work, and that this would necessarily be very objectionable to the Government.

For this reason it is believed inadvisable for the Government to withdraw or modify its request to Hon. Julius M. Mayer to have the suit postponed. The request of the [fol. 2471] Government, however, is not to be construed as making it unnecessary for the telephone company's counsel to use every effort to obtain the services of satisfactory experts who are free to undertake the work.

Very respectfully.

R. S. Griffin, *Engineer in Chief, United States Navy, Chief of Bureau.*

Mr. Drury W. Cooper, *55 Liberty Street, New York, N. Y.*

July 20, 1918.

SIR: This department is informed that a suit is pending before you in which Peter Cooper Hewitt is claiming that the vacuum tubes furnished by the American Telephone & Telegraph Co. embody certain inventions owned by him, and that you desire to be informed as to whether or not the experts available to the American Telephone & Telegraph Co. for consultation and presenting the situation to the court are free to take up this work, or whether, on the contrary, their services are required by the Government.

For the war necessities now existing this department requires and is obtaining the services of all of those who are skilled in vacuum-tube matters in the organizations of the American Telephone & Telegraph Co. and of the Western

Electric Co. (Inc.), as well as those connected with other organizations. It would be prejudicial to the public interests to permit anyone having such knowledge of the operation of these devices in telephony and allied work as would fit him to assist the court and the defendant in the presentation of this case to devote to the case the time which would be necessary for this purpose.

Moreover, the experts of the American Telephone & Telegraph Co. and of the Western Electric Co. (Inc.) and others are engaged in cooperation with this department in highly confidential work involving vacuum-tube operations along lines deemed to be of the highest importance in connection with the prosecution of the present war. This work must be proceed; any testimony given by persons having knowledge of this confidential work, even though not specifically directed to it, would be inadvisable.

For these reasons this department requests that no further steps be taken in this litigation during the present emergency.

Copies of this letter are being forwarded to Mr. Drury W. Cooper and Mr. Charles Neave.

Respectfully,

Josephus Daniels, Secretary of the Navy.

Hon. Julius M. Mayer, United States District Court, New York, N. Y.

January 18, 1918.

Gentlemen: From information received by the department from the Bureau of Steam Engineering it appears that the Government's interests are indirectly involved in the suit of the National Electric Signalling Co. against the Marconi Wireless Telegraph Co., of America, on account of alleged infringement of two patents to Reginald A. Fessenden, Nos. 918306 and 918307, covering improvements in high group frequency radio apparatus, and that certain information of record in the department or within the knowlege of experts in the department's employ will be of considerable value in connection with the trial of said cause.

In view of the demands made on the entire force of the department's employees under existing conditions it is not possible that the Government's interests as affected by said

suit can be given the attention requisite to a proper disposition of the matters in issue and as the department's interests will be affected by the outcome of the case analogously with those of the defendant, it is requested that you, in the public interest, ask the court to stay all proceedings for the duration of the war.

Very respectfully,

Franklin D. Roosevelt, Assistant Secretary.

Messrs. Sheffield & Betts, Counsellors at Law, 52 Williams Street, New York City, N. Y., Attorneys for Marconi Wireless Telegraph Co.

[fol. 2472] April 20, 1918.

Sir: I had the honor to address you under date of February 13, 1918, in regard to the suit of the International Radio Telegraph Co. (formerly S. M. Kintner and H. M. Barrett, receivers of the National Electric Signaling Co.) against Marconi Wireless Telegraph Co., now pending before you in the United States District Court for the District of New Jersey. In this letter it was stated:

"The department does not wish to be understood as requesting a stay of proceedings that would interfere with the making up of the record up to the point where testimony of Government witnesses already of record is incorporated in the case, but in view of the stress of present activities of the department, the absence of some of its experts in foreign waters, and the heavy burden of duties now engrossing the entire time of others, it is believed that the Government's interests would be materially prejudiced, unless given the opportunity after the termination of the war to have incorporated into the record such further testimony as it may deem appropriate and relevant to the patents in suit."

It is the understanding of the department that the record in this case has been now made up to the point where testimony of Government experts already of record has been incorporated therein, but in view of the stress of present activities of the department and the absence of some of its experts in foreign waters and the heavy burden of duties now engrossing the entire time of others, it is believed that the Government's interest would be materially prejudiced, unless given the opportunity after the termination of the

war to have incorporated into the record such further testimony as it may deem relevant and proper to the patents in suit. Hence, it is for the public interest that further proceedings in this cause be suspended for the duration of the war.

Josephus Daniels, Secretary of the Navy.

Commander Loftin: Mr. Chairman, I will take up the general situation first, and then I think the details can be brought out by questions put to me and other members of the board who have been working on this proposition for several years.

Congress and the heads of the several departments are not interested directly in the details of the hundreds of patents which have been considered by this board, and must, of necessity, abide by the opinion of this board or any similar organization; but they are interested in what, in fact, is accomplished by such a board.

There are approximately 2,500 United States patents in this art, all of which were living during the period covered by the board. All of these have had to be considered in one way or another; if not directly as patents under which claims are made, then as to their bearing on patents under which claims were made. In addition, hundreds of foreign patents and hundreds of United States and foreign publications have been sought out and considered in relation to their effect on those patents presented in the claims.

The claimants did not know precisely just what the Government had used, and many of them brought claims under all patents, with the result that the board had to laboriously proceed through several hundred patents, pick out those under which it was evident there was no infringment, and then by hearings with claimants, long drawnout, eliminate the chaff.

The board finally came down to a real serious consideration of 149 patents. This consideration involved searches of the art, writing of long reports, receipt of briefs from claimants, hearings, more briefs, revised reports, and then an accounting on those patents considered good, which were 27 in number, with much discussion following as to the methods of accounting and the effect of decisions thereon.

[fol. 2473] The final number of patents found by the board to be of substantial value was 27. This does not mean there

were not other patents which had been used in small ways, but most of the claimants, recognizing the scope of such an investigation, and realizing that it would draw out the investigation to such an extent by considering minor patents, agreed in advance, if they succeeded in getting a settlement on some of their basic patents, that they would then lump them all and release to the Government all minor patents.

The Chairman: Of these 2,500 patents claimed, were a goodly number allowed before the board was organized?

Commander Loftin: Allowed where?

The Chairman: Or approved by the Government as being valid patents?

Commander Loftin: They were allowed by the Patent Office; yes, sir.

The Chairman: About how many of those patents were there, of the 2,500 that were allowed?

Commander Loftin: Actually about 2,500 were allowed by the Patent Office, but only 27 major patents were allowed by the board as having been used by the Government. We were not asked to consider some minor patents; they were thrown in, if settlement could be reached on the major patents.

Mr. Parker: That is to say, there were minor patents owned by the owners of the major patents?

Commander Loftin: Yes, sir.

Mr. Parker: Then there were a lot of outside patentees who were getting nothing under this settlement?

Commander Loftin: We have asked practically everybody who was suspected of owning a radio patent to come before the board and present evidence.

Mr. Parker: Will they all be released?

Commander Loftin: They will be released, those that have been favorably considered by the board.

Mr. Parker: There are a number which have not been favorably considered; are they going to be released?

Commander Loftin: Most of them will be included in the releases, along with the major patents. For instance, the Marconi Co. has about 350 patents. They presented only four patents finally to the board. The board allowed three of those four patents. They will include in their release to the Government all of the 350 patents that they own, and also the one not allowed by the board, so that it will be a complete and sweeping release of that company on practically 350 patents.

Mr. Parker: What about the Deforest Co.; that was a rival company?

Commander Loftin: We have not succeeded in reaching a settlement with the Deforest Co. In 1917 the Deforest Co. sold to the American Telephone & Telegraph Co. the exclusive rights under their patents. Most of the apparatus bought, which was covered by those patents was bought during the war; if it was prior to the war it was bought from Deforest himself, so there would be practically no allowance to Deforest prior to the time he made this sale to the American Telephone & Telegraph Co. He has contended that he [fol. 2474] has a claim subsequent to such transfer to the American Telephone & Telegraph Co. That matter was submitted to the Attorney General by the board for an opinion as to whether or not he had a legal claim. So far he has failed to convince the Department of Justice that he did have a legal claim. He had many hearings there, and he finally decided that the question involved was so difficult that he would withdraw his claim from the board and submit it to the Court of Claims, later on, if he so desired. So he stands now with his claim withdrawn from the board on a technical, legal question.

Mr. Parker: Can we not force him into the Court of Claims so that we can have done with the question for good?

Commander Loftin: There is no necessity to force him into the Court of Claims; he will go there if he thinks he has any substantial claim.

The Chairman: In the draft of the bill which the departments sent to me I have suggested to one or two of my colleagues on the committee, with whom I have talked, that we put a limitation in there compelling them to present all their claims within a comparatively short length of time, or lose their rights altogether, and that is the only way to handle the question, otherwise the matter would be pending for years, and no committee of Congress at this time wants that kind of a condition to prevail.

Commander Loftin: I might add here that we have already obtained a release from the American Telephone & Telegraph Co. for all claims that they have on the Deforest patents, under which they acquired exclusive rights on March 17, 1913.

The Chairman: About how many claims are included in this bill out of the 2,500 patents that were filed?

Commander Loftin: This will settle all claims which have been presented to the board, except that of the Deforest Co., which has been withdrawn, and one or two minor claims, which were not found by the board to have substantial merit.

The Chairman: What was the value of the Deforest claims as presented by them?

Commander Loftin: He has filed suit in the Court of Claims in which he puts the value at $2,000,000.

The Chairman: So then, as I understand you, claims to the value of $14,000,000 in the aggregate, or thereabouts, were filed with you. Of that $14,000,000 how much is unrepresented in the report you now make?

Commander Loftin: Deforest has $2,000,000, and there is one other claim for $150,000.

The Chairman: So that in making a settlement of these claims and paying $2,500,000 you are practically wiping out approximately $12,000,000 worth of claims?

Commander Loftin: But that $14,800,000 only represented the statements of 7 out of 24 claimants. The other 17 did not state any particular sums, or have not filed suits in the Court of Claims from which we could arrive at figures.

The Chairman: Then you assume that the $2,500,000 which you propose to be paid in settlement, will cover a much greater value than $14,000,000?

Commander Loftin: Easily double that.

[fol. 2475] The Chairman: You may proceed.

Commander Loftin: Such a task has been stupendous, and has required a force of experts—expert to begin with, but which became more expert daily in its specific task as it gained knowledge from experience.

Consider the chaos that would have existed if such a task (the serious consideration of 149 patents of a difficult art) had been presented to a number of courts in different places and at different times; for a single patent could be the cause of half a dozen suits in order to reach the numerous contractors for the Government; and then, after the patents had been sustained, the long drawn out procedure of accounting in each case, each accounting duplicating in many respects accountings in other jurisdictions.

I predict that under our judicial system, and with the extreme difficulty in presenting patent cases, that the task could not have been covered in the courts in 25 years, in the same comprehensive but centralized method of the board.

Patent litigation is a parasite on the development of the

art. Every patent attorney has to be assisted by a whole corps of experts, and I could cite you examples of several recent cases, apparently very simple, which in effect practically stopped the operations of several companies because their engineers were being used by the lawyers as experts.

This art is just coming to the point where it is to justify its inception as one of the blessings to mankind, and nothing should be allowed to interfere with the commercializing plan mapped out. It has proved its value from a military point of view during the war. It has had a great commercial value in the past, but its future is almost without limit, and should be realized, by subsidy, if necessary, rather than by placing useless stumblingblocks in its path.

I could easily make you a table showing how just one of the patents considered by the board could be the subject of seven or eight suits, with reasonable hope of substantial recovery, and when we take all the patents which would have the same reasonable hope of recovery, and show the combinations of suits which could be brought, it would easily reach the hundred mark.

The Chairman: Would it be very difficult to make that kind of a table?

Commander Loftin: No, sir.

The Chairman: The House wants to know about that. If you could take one of these claims and show just exactly what could be done under the patent law, and insert it in the hearing, I am sure the committee will appreciate it very much.

Commander Loftin: That matter is really very simple. For instance, we can take just one of the patents that the board has found to be good, and we can say that the Government has bought apparatus from at least eight contractors employing that particular patent. For that patentee to reach those contractors and get from them what the law allows him—their profits—he would have to file a suit against each one of them, in most cases in different jurisdictions.

The Chairman: If the United States court found that a patent was valid and rendered a decision in favor of the [fol. 2476] holder of the patent, would not the other contractors immediately confess judgment, because the opinion in the one case, affirmed, of course, by the higher courts, would be a precedent in the other cases?

Commander Loftin: That always has an influence on the fellow who is subsequently being sued; but in most of these cases the Government has saved the contractors harmless, so that we would really have to go out into the district courts and watch those suits and see that the contractor who was being sued did not throw up the case (he having been saved harmless by the Government), leaving a situation wherein he could come back to the Government and say, "Reimburse me; I have lost in this court on that particular contract," and the patent owner then having secured judgments in the district courts, could come to the Court of Claims and file a suit against the Government for the use of that apparatus. So that it easily runs up in some cases to 7, 8, 9, or 10 suits. If we take the 27 patents and multiply that number by 5, allowing a factor of safety on the number of suits being brought, that would easily total over a hundred suits.

The Chairman: That would make 135.

Commander Loftin: Yes. That table is not very difficult to make. I could name specific patents and specific apparatus which was involved, and specific contractors if it would be of any value to the committee.

The Chairman: We will appreciate it if you will kindly put that in the hearing.

Mr. Morin: The validity of these patents is not questioned, is it?

Commander Loftin: In this bill?

Mr. Morin: There is no question as to the validity of the patents?

Commander Loftin: On some of them we did question the validity and made no allowance on them, and our figures have been accepted by the claimants.

Mr. Morin: The allowance has been based on the use of the patents that have been found valid?

Commander Loftin: Yes; and the manufacture also. This whole settlement includes the contractors for the Government as well as the Government, the particular necessity for that being that the Government has agreed in many cases to save the contractor harmless. Now, under the act of 1918 we have the entire responsibility anyway.

Mr. Morin: You have not allowed any claims where the validity of the patent is in doubt?

Commander Loftin: No, sir; unless the doubt was such that it could reasonably be resolved in favor of the patentee.

I might say here that I am informed that the courts generally lean over backward to sustain a patent, but I do not think we have gone quite that far. We have required them to come somewhere near the middle ground before we have held that the patent is good. But the courts are very liberal with inventors and will generally resolve a very strong doubt in their favor.

The Chairman: The men who own patents think that the infringers have things all their own way. You may proceed with your statement.

Commander Loftin: The Government has largely held the contractors harmless, through war necessity, and would [fol. 2477] naturally have to defend all the suits to keep indifferent contractors from forfeiting them, and I believe this would mean new quarters for the Attorney General, with a patent department as large as his whole present organization.

In practice, then, this robs patent attorneys of a most promising, lucrative field of occupation for years to come, and saves untold expense in litigation, both to the Government and to patent owners. It practically frees the entire field of prospective litigation and allows the engineers of the companies to go about their legitimate business of improving and perfecting, rather than trying to save from the scrap heap what has been done before. It would practically ruin the Government organization, as radio experts are extremely few, and the Department of Justice would commandeer everyone for litigation.

The Chairman: Have you heard from the patent attorneys?

Commander Loftin: We have had many of them before us.

The Chairman: Are they in favor of this report?

Commander Loftin: Yes; they are quite reasonable about it.

It encourages an art for it to from time to time see that some compensation is being paid for the work being done. The Government has no too good reputation as to its relation to inventors, and yet this method does not encourage the undeserving, as every claim has been sifted down to its real merit.

This board has not aroused any hard feelings. Litigation always does. In our dual status of being court and defense,

we have had to keep open minds, and I believe we have won the confidence of every claimant who has been before us.

By our work the Government knows just where it stands in the radio-patent situation, and through this knowledge has been enabled to negotiate some very desirable patent arrangements for the future; yet all of this good work could be readily stultified if no settlement was had out of this board's efforts and the whole field thrown into litigation.

The Government stopped all litigation during the war by appeals both to litigants and courts. The board stopped it during its work in order to leave the situation in status quo, as it would have been impossible to deal with a situation constantly changing.

I have no knowledge of any substantial reward to any patent in this art. There have been many suits, but the operators heretofore have been financially weak and the judgments have not meant anything.

The Chairman. Did I understand you to say if they had secured judgments when you make this settlement those possible judgments will all be wiped out?

Commander Loftin. Yes, sir; as far as the Government apparatus is concerned. It does not seem that, as far as some commercial company is concerned, which has been operating commercially.

The Chairman. It is only the Government we are interested in.

Commander Loftin. We feel that the operations have been so small that if they settle with the Government it will stop the other suits and allow those men to go ahead in the matter of development. While great advance has been made, there are many problems to be solved, and all that can be done to help solve those problems is going to be of value.

(tol. 247s) It may be of particular interest to know that while the interallied communications conference was in session here in Washington last fall a number of representatives of the British Government at that conference, who were also radio men in Great Britain, learned that such a board was in progress here. They came to us and said they had quite a similar situation in Great Britain, and having learned of our board they would like to have the details as to procedure, what we proposed to do, and how far we had gone, etc., so that they might inform the British Govern-

ment of this form of procedure. After they returned home we learned informally that they had organized such a board in Great Britain.

The Chairman: That was subsequent to the time when they were here?

Commander Loftin: Yes, sir. We had our naval attaché in London inquire as to whether or not that was a fact, and we had a brief report saying that such a board had been organized, but with a personnel much more widely known than the personnel who compose this board.

The Chairman: That shows that they learn things from other countries.

Commander Loftin: They are using what we call in the Navy "deep draft" men—big men.

The Chairman: We can probably learn from other countries, too.

Commander Loftin: Such a board is in progress, and they intend to go further than merely the radio art and are going into other arts in an endeavor to settle numerous claims which have been brought.

The Chairman: Do you think that was the reason why they came to no agreement whatever in this matter of cable transmission—telegraphic transmission?

Commander Loftin: You mean while the conference was in session here?

The Chairman: Yes.

Commander Loftin: They came to many agreements on many points.

The Chairman: On the principal point they did not come to an agreement, or rather they determined to leave the matter to their ambassadors, and they have come to no conclusion yet.

Commander Loftin: They are to proceed again this summer.

The Chairman: And the next summer, and the summer after that, I imagine. You may proceed.

Commander Loftin: The claims which have been stated are $14,800,000, by 7 out of 24 claimants. If all of them had stated an amount, it would probably have been thirty or forty million dollars.

We think it represents a good showing as to the accuracy of our work to pare these claims down to approximately

$2,500,000 and still keep the claimants happy. They are all with us now; you will find them probably putting in a word for themselves, as they have an opportunity, and we certainly see no objection to that. They have worked hard with us and have met every request that the board has made, and we think it is only fair that they should have an opportunity to state their side of the case from time to time, as considered advisable.

The Chairman: Are the Deforest Co. and the other company which you named the only two that are out of this settlement now entirely?

[fol. 2479] Commander Loftin: No, sir; not entirely.

The Chairman: I think the committee would like to know, and it is desirable that we tell the Members upon the floor of the House, just how many claimants are willing to stand by this agreement.

Commander Loftin: I will go through the list of claimants and tell you just what we have done in each case.

In the case of the Vreeland Apparatus Co. we have not made any recommendation as to their claim.

The Cairman: Have you considered it?

Commander Loftin: We have considered their claim very fully, and their claim has also been considered in part—not all their patents—but two out of four of their patents were also considered by the Munitions Patents Board along with us, and their claim was rejected also by that board.

The Chairman: Was it rejected by your board?

Commander Loftin: Our board and the Munitions Patents Board, as far as they considered their claim, which included two out of four patents. We considered four patents, but two of them for special reasons went to the Munitions Patents Board also.

The Chairman: You have rejected it, so far as you are concerned?

Commander Loftin: Yes, sir; we have rejected it.

Mr. Parker: Might I ask you this question, and that is, whether you will settle if the Government used any of the machinery? If they sold the machinery, of course they can not charge for its use.

Commander Loftin: No, sir; they were not a manufacturing company.

Mr. Parker: But suppose the Government simply used the machinery?

Commander Loftin: They were a patent holding company. Now, take the case of the Marconi Wireless Telegraph Co. We reached a settlement with this company and will secure an absolute release from that company under their entire patent situation, which includes some three hundred and fifty and odd patents up to the time that company transferred its holdings to the Radio Corporation of America.

Mr. Wright: Would it not be well to have the amounts of the claims set out, Mr. Chairman, and also the amounts allowed?

Commander Loftin: Where the amounts have been stated we can do that.

The Chairman: Will it take a great length of time?

Commander Loftin: I have sent to you, Mr. Chairman, a draft of the preamble of our report to the several secretaries. That goes into the general phases of the board's work, including the proposed allowances to the several companies. That is not quite complete, but I see no objection to its going into the record, if you desire to have it printed.

Mr. Garrett: Does that include the list of the amounts claimed, and also the amounts allowed?

Commander Loftin: Yes, sir.

The Chairman: You have that in the report, a copy of which you sent to me?

Commander Loftin. Yes, sir.

Mr. Morin: Have you a list of the awards made?

Commander Loftin: Yes, sir.

[fol. 2480] Mr. Morin: It seems to me if that is included in your statement, it would be well to include the entire matter.

Commander Loftin: That is included in the statement which I sent to the chairman, and that will cover the whole matter, unless these amounts stated would bring out some points you would want to ask questions about.

Mr. Parker: Does your statement show whether the machinery was purchased, or whether you made your own machinery?

Commander Loftin: Practically all our apparatus has been made by commercial concerns. We have made a small amount in the Government navy yards.

Mr. Parker: Was any of it made by the patent companies themselves?

Commander Loftin: In a good many cases; yes.

The Chairman: That would all be shown in the statement which you have?

Commander Loftin: We have not shown in our statement which companies are manufacturing and which, apparently, are straightout patent holding concerns, or individuals, who have no facilities for manufacturing.

Mr. Parker: What I meant was, if these people furnished you the machinery and you bought it, you would be free from any royalties.

Commander Loftin: We have taken care of that; we have made no allowance where they have furnished the apparatus themselves.

The Chairman: If there is no objection, the report you refer to may be included in the hearing at this point.

(The report referred to is as follows:)

Report of the Interdepartmental Radio Board as to Claims Against the United States by Owners of Radio Patents

Washington, D. C., *May 31, 1921.*

The Secretary of War,
The Attorney General of the United States, and
The Secretary of the Navy.

This board is comprised of representatives appointed by the Secretary of War, the Attorney General, and the Secretary of the Navy, and constituted as follows:

Lieut. Commander Edward H. Loftin, United States Navy, president, and Commander Stanford C. Hooper, United States Navy, representing the Navy Department.

Robert H. Young, Esq., recorder, and Capt. Guy Hill, United States Army, representing the War Department.

Harry E. Knight, Esq., representing the Department of Justice.

(See "Precept," Paper A.)

History

The steps leading up to the appointing of this board were the following:

Prior to the entry of the United States into the war a single suit involving radio patents had been brought in the

Court of Claims against the Government, namely, that of the Marconi Wireless Telegraph Co. of America against the United States, filed July 29, 1916. At this period the contracts of the Government, in general, including those relating to radio apparatus, required that the contractor should indemnify the Government from any loss arising out of claims for infringement made by reason of the infringing of the contractor's apparatus, and the responsibility of the Government was specifically stated by the act of June 25, 1910 (ch. 423, 36 U. S. Stats., 851).

In January and February, 1918, the Western Electric Co., prior to final decision by the Supreme Court in the Cramp [fol. 2481] and Simon cases below mentioned, had insisted, as to its contracts with the Government, that it (Western Electric Co.) be held harmless in any patent litigation. In one such contract, for example, relating to a radio apparatus designated as an audio frequency amplifier, the supply officer at the navy yard in New York was instructed to award the contract to the Western Electric Co., subject to the following condition:

"The apparatus mentioned herein being required without delay by the United States Government said apparatus is furnished in this emergency without investigation of outstanding patents, upon the condition (to which the United States, in placing its order, agrees) that the United States will save the Western Electric Co. (Inc.) harmless from all claims for infringement of patents on account of the apparatus so furnished, the Government assuming with the patentees direct all responsibility for said patent infringement."

On March 4, 1918, the United States Supreme Court, in the cases of William Cramp & Sons Ship & Engine Building Co. *v.* International Curtis Marine Turbine Co. (246 U. S., 28) and Marconi Wireless Telegraph Co. *v.* Simon (246 U. S., 46), having rendered the opinion that in certain cases contractors with the Government were not protected by the act of 1910 from independent liability, it was represented to the Government, and particularly to the War and Navy Departments, that contractors could no longer safely undertake the warranty against infringement. See in this connection the letter from Deforest Co., dated March 14, 1918. Similar letters were received from the National Electrical

Supply Co., the Wireless Improvement Co., Emil J. Simon, the Wireless Specialty Apparatus Co., Kilbourne & Clark Manufacturing Co., and the Sperry Gyroscope Co.

The contracts with the Western Electric Co., referred to in said letter, had been made prior to the rendering of the decisions in the Cramp and Simon cases, the Western Electric Co. having (as already stated) made their bids in certain cases only on condition that such warranty be given. At this time there had been called to the attention of the Government claims of various companies owning patents for radio apparatus, particular stress being laid upon claims arising under adjudicated patents of the Marconi Wireless Telegraph Co. of America, the International Radio Telegraph Co., and the Deforest Radio Telephone & Telegraph Co.

On March 29, 1918, the Acting Secretary of the Navy caused to be addressed to the Deforest Radio Telephone & Telegraph Co. a communication accepting certain responsibility on the part of the Government for the protection of contractors against patent claims and by direction of the Secretary, the Bureau of Supplies and Accounts, Navy Department, was, on April 3, 1918, notified that letters of similar purport to that sent to the Deforest Co. would be sent by the department from time to time to other contractors where it appeared that such action was necessary, in addition to those mentioned in the first indorsement of the Solicitor for the Navy Department on April 3, 1918.

The Secretary of War issued similar orders and the Secretary of the Navy did likewise in several additional instances.

In order to ascertain and define the obligations which were being assumed by the Government under these guaranties, conferences looking to the reaching of an amicable agreement were had with the several companies and particularly with the Marconi, Deforest, and International Cos.

On June 14, 1918, a conference was held between a representative of the War Department and the Marconi Co.

Negotiations also proceeded with the Deforest and International Cos., and the claims of other patentees which had arisen or might arise were brought to the attention of the War Department and Navy Department and litigation began or was threatened involving the Government directly or indirectly.

In order that the action of the War Department and the Navy Department in reference to claims made to them and the action of the Department of Justice in regard to the litigation pending or proposed might be coordinated, it was, on the 13th of July, 1918, proposed by the patent section of the Bureau of Aircraft Production to the Secretary of War that a letter be addressed to the Secretary of the Navy and the Attorney General proposing the appointment of a board representing the three departments to investigate and negotiate settlement; and favorable responses having been given and action taken thereon, the present board was constituted, and, after various changes in personnel, it is composed of the representatives above stated.

Among considerations influencing the constitution of a board to which might be submitted all claims under radio patents were the following:

It was considered that under the conditions established by the acts of 1910 and 1918 the Government would be in- [fol. 2482] volved in a multiplicity of suits under patents and that these would be different in character, depending upon the time at which the infringement complained of occurred and, in some cases, upon the question of whether the Government or the contractors with the Government were original or contributory infringers. The varying conditions of warranties affecting different contracts, some warranties being by the contractor and some by the Government, in so far as liability of patent infringement is concerned, introduced a serious complication. Under these warranty contracts the Government naturally became interested in suits pending anywhere in the United States involving alleged infringement of letters patent under which claims might be made against the Government.

These questions became particularly important in the radio art, which involves considerable difficulty in understanding its principles and in making them clear to any court not technically trained. The art is, furthermore, new and rapidly developing, so that the condition of patent protection is in a state of flux, and the entire field of accounting is embraced by still living patents. The number of claimants in this line and the patents involved were numerous, the contractors were also numerous, and the variation in forms of apparatus was and the conditions of the contracts were such that a claimant for compensation under a patent was in the position in some instances of being a warrantor

to the Government under all patents but his own. The great importance of the radio art to the conditions of modern war and the necessity for ignoring everything but efficiency and speed in securing equipment produced an amount of infringement upon radio patents in the last few years all out of proportion to what would have occurred in ordinary times.

A board comprising representatives of the several departments involved would consolidate the accounting into a single process which, in other event, might have had to have been repeatedly repeated for proceedings involving different departments of the Government, different patents and different jurisdictions. It would enable the coajoint consideration of the various claims and the various patents and thus protect the Government from having to pay multiple compensations for the same installation, for each patentee could be counted upon to urge in court the exclusive importance of his invention, and if each were granted compensation without the consideration of the claims of other patentees, the Government would undoubtedly be involved by successive suits in a total amount out of all proportion to what would be involved if all claims were presented to a single tribunal and each compelled to take his fair proportion of a total sum, for it must be admitted that the compensation due to a patent can not go beyond the value which the invention of that patent has added to preexisting art, and that value is most safely measured by the profit that can be made upon the improved machine, whether by the patentee or by the purchaser as compared with what can be made with prior machines. This sum, being determined either accurately or roughly as the circumstances of the case admit, must be allocated to all patented inventions contained in the machine and properly between them with some attempt of relative valuation and after deduction, also accurately or roughly as the case permits, of the share that is due to old or unpatented parts of the machine.

The saving by such a proceeding of delays and expenses of numerous litigations in numerous courts is obvious, and it may be assumed that if the Government by such a proceeding can ascertain the amount acceptable to claimants and substantially equivalent to what they could expect by continuance of litigation, the Government will have been fully justified by reason of the saving of the time of its personnel and the expenses involved in litigation.

The Interdepartmental Radio Board thus constituted held its initial meeting and organized on August 16, 1918, and began the preparation of a complete detailed statement of the radio apparatus which had been bought, constructed, and used by the War and Navy Departments, segregating the apparatus as much as possible with relation to the patent art as it has progressed.

Prior to the signing of the armistice in November, 1918, the operation of the board was interfered with by the detailing of its members in war operations. On February 12, 1919, a letter was addressed to each of a list of patent owners.

The Wireless Improvement Co., J. S. Stone, Cutting & Washington, and Cooper Hewitt Electrical Co. submitted no claim. The following parties responded that they had no claims to be satisfied or negotiated: Federal Telegraph Co., General Radio Co., Liberty Electric Corporation, Moorhead Laboratories (Inc.), American Radio & Research Corporation, Westinghouse Electric & Manufacturing Co., Kilbourne & Clark Manufacturing Co.

[fol. 2483] Claims for compensation were made by the following:

1. Vreeland Apparatus Co.
2. Marconi Wireless Telegraph Co.
3. International Radio Telegraph Co.
4. Deforest Telephone & Telegraph Co.
5. Louis Cohen.
6. E. H. Armstrong.
7. Emil J. Simon.
8. Sperry Gyroscope Co.
9. American Telephone & Telegraph Co.
10. Reginald Fessenden.
11. Clapp-Eastham Co.
12. Wireless Specialty Apparatus Co.
13. Lowenstein Radio Co. (Inc.).
14. Dubilier Condenser Co.

The following claims were added later:

15. General Transmission Co.
16. John Firth.
17. H. M. Horton.
18. National Electrical Supply Co.

19. Joseph Raes.
20. Title Insurance & Trust Co.
21. Peter E. Stogoff.
22. J. Harris Rogers and H. H. Lyon.
23. J. Harris Rogers.
24. American Mechanical Improvement Co.

An additional circular letter, inquiring as to the condition of cross licenses affecting the patents involved, was sent May 15, 1919, to the several claimants.

The answers to this second circular letter were before the board when the individual claims were considered.

The board thereupon proceeded to consider the several hundred patents set forth in these claims, and on September 25, 1919, had progressed so far with this examination that a letter was sent to the several claimants appointing hearings.

Later notices were sent to the remaining claimants and in due course the claimants all appeared before the board and hearing was had orally in each case. During the discussion of the claims with the various claimants, numerous patents were eliminated by withdrawal of claims thereon, so that there were left for consideration by the board claims based only on the following:

	Number of Patents
1. Vreeland Apparatus Co.	4
2. Marconi Wireless Telegraph Co.	4
3. International Radio Telegraph Co.	29
4. Deforest Radio Telephone & Telegraph Co.	62
5. Louis Cohen	1
6. E. H. Armstrong	1
7. Emil J. Simon	1
8. Sperry Gyroscope Co.	2
9. American Telephone & Telegraph Co.	70
10. R. A. Fessenden (not formally presented).	
11. Clapp Eastham Co.	1
12. Wireless Specialty Apparatus Co.	12
13. Lowenstein Radio Co. (Inc.)	2
14. Dubilier Condenser Co.	4
15. General Transmission Co.	1
16. John Firth	1
17. H. M. Horton	1

	Number of Patents
18. National Electrical Supply Co.	2
19. Joseph Raes	1
20. Title Insurance & Trust Co.	1
21. Peter E. Stogoff	1
22. J. Harris Rogers and H. H. Lyon	2
23. J. Harris Rogers	5
24. American Mechanical Improvement Co.	1

This board has not in its consideration of the various claims that have been brought before it assumed to exercise a judicial function. It has had in view its position as a [fol. 2484] governmental agency, acting on the part of the Government, for ascertaining such reasonable compensation as may be allowed to the various claimants on a basis of settlement without suit, and in each of the conclusions it has reached upon controversial points it has given proper weight to the consideration that both the Government and the claimants will by acceptance of the board's conclusions avoid the expense, delays, and uncertainties of such litigation, and any conclusions which it may reach favorable to any claimant are not to be considered as binding upon the Government, nor as an expression of the Government's or of the board's conclusions on any of these controversial points, in the event that the action of the board does not lead to a final settlement without further litigation.

It also has been had in mind by the board that settlement for the amounts determined to be due the several claimants is to dispose of all claims of infringement arising out of the purchase, use, and sale of patented apparatus and methods, whether against the Government or against contractors with the Government.

The figures arrived at necessarily have been merely approximate. In some cases figures have been estimated from data in hand. In others, on account of lack of specifications or inaccessibility of apparatus for examination, the board has had to reach a conclusion based on verbal reports of officers.

The ascertainment of reasonable compensation has involved various difficulties.

Difficulty is found in determining the period of life and usefulness of individual instruments, and it is not known

and can not readily be ascertained in individual instances how long the period of usefulness is. It is difficult, therefore, to say whether an instrumentality purchased in 1914 may have gone out of use by 1915, at which time it may be there first issued a patent which covers it. It also is difficult of ascertainment whether the article purchased in 1914 was actually put in use in that year or was not actually put in use until 1917, or was ever put in use. This problem can be satisfactorily solved only by awarding the compensation upon the purchase of the article independently of the time and actuality of use, and this method has, in the main, been followed.

It has been ascertained by the board that while a proportion of the cost which might be allotted for compensation by way of royalty can be determined in individual instances of orders of specific instruments, in a large proportion of cases the relative cost of that instrument is not accurately ascertainable where it is incorporated in complete sets or parts of sets.

The board in arriving at a determination of the proper weight of the several patents, infringement of which has been declared, and of the value thereof in affecting reasonable compensation to the claimant, has had, in the first place, to consider whether the specific invention was general in character in so far as its use affected the value of the operation of the entire system or was so local that it involved merely the substitution in one part of the system of a device having for its reason for selection a mere improvement in convenience, cheapness, or other characteristic not involving a modification in operation of the system regarded as a whole. While an improvement might seem, so far as its claims are concerned, to be limited to the specific arrangement of certain elements in the entire wireless installation, where the result of this combination has been so important in affecting the successful operation of the entire system that an adequate return to the inventor would not be secured by awarding to him the proportion of the cost of that specific part of the apparatus, recognition is given by the board to this fact in determining that in such cases the royalty to be allotted to the claimant is to be as widely distributed in the apparatus as is the result of his improvement, or where the improvement is local the allotment of the royalty is equally localized.

In determining the proper amount of royalty in these two cases the board has had recourse to the several decisions of the Court of Claims in determining on what had been considered in individual cases the fair amount of royalty, and has also had in view the practice in commercial establishments in fixing a fair amount of royalty in individual cases, recognizing that the determination of a specific royalty in any individual case is largely an empirical matter and that the conclusions herein represent only a consensus of the opinion of the members of the board derived from the circumstances affecting each individual case.

Copies of all patents and publications referred to are made a part of the files of the board, being too numerous to be made a part of this report.

[fol. 2485] A list of prior litigations on radio patents, approximately complete, is found in paper No. 11.

A list of cases pending against the United States on radio patents in the Court of Claims is found in paper No. 12.

The claim in which amount claimed has been stated are as follows:

Marconi Wireless Telegraph Co. of America	$6,000,000
Deforest Radio Telephone & Telegraph Co	2,000,000
Dubilier Condenser Co	60,000
Emil J. Simon	100,000
John Firth	50,000
Wireless Specialty Apparatus Co	6,500,000
Title Insurance & Trust Co	150,000
Total	14,860,000

The following claimants, while not expressing the definite sum of their claim, demanded a monetary award:

Vreeland Apparatus Co.
International Radio Telegraph Co.
Louis Cohen.
Edwin H. Armstrong.
Sperry Gyroscope Co.
Lowenstein Radio Co.
General Transmission Co.
H. M. Horton.
National Electrical Supply Co.
Joseph Raes.
American Telephone & Telegraph Co.

R. A. Fessenden (not proceeded with).
Clapp Eastham Co.
Peter E. Stogoff.
Dubilier Condenser Co. (on one patent not included in suit in Court of Claims).
J. Harris Rogers & H. H. Lyon.
J. Harris Rogers.
American Mechanical Improvements Co.

As the total purchases and manufacture of radio apparatus, during the period covered by the accounting—as will appear later in this report in discussing the accountants' figures—amounted to $40,425,404.36, the total claims, considering the figures mentioned in discussion by the claimants not presenting definite figures, represented fully 50 per cent of the total cost of apparatus.

The various patents involved will be found more particularly identified in connection with each of the following reports. In the case of each claimant the various patents have been carefully examined with the aid derived from briefs or oral arguments submitted, and the board has, where necessary, examined the history of the patent as disclosed by the Patent Office record and reports of litigation, and has made as extensive a search of the prior art as has seemed necessary in each case. It has also made an extensive inquiry into the radio apparatus purchased or manufactured by the Government, examining the various apparatus where necessary and securing information as to actual details of their construction and operation from Government employees best acquainted therewith.

Résumé

The following claims are denied by the board:

Marconi Wireless Telegraph Co., reissue patent 11913, coherer as receiving device.

International Radio Telegraph Co.:

742780, 752895, 1074423, 1092049, 1059666, 1156677, 1184843, interference preventers.

727331, reissue 12145, eletrolytic detector.

706,745, receiver arrangements, stiff circuits.

730753, charging aerials from direct current source without interruption.

979144, 1020632, 1101914, 1101915, horizontal antennae of small elevation.
1050728, absorbing circuit, claim 9 of patent.

[fol. 2486] Wireless Specialty Apparatus Co.:
1118228, noncopper compounds.
876996, loop antenna.
1213250, detector circuit.
893811, Leyden jar.
1127921, tap tuner with micrometer variation.
904222, chemical compounds.
1104065, cat whisker (nonuse).
1104073, cat whisker.

National Electrical Supply Co., design patent 48638, hand generator.

Joseph Raes, 1099861, portable tower for radio field station.

Vreeland Apparatus Co.:
829447, 829938, oscillion circuit.
1245166, combination of continuous wave transmitter with signals controlled by change of frequency and a heterodyne receiver.
1239852, heterodyne receiver.

Dubilier Condenser Co., 1279850, buzzer transmitters.

General Transmission Co., 1216615, quenched gap circuit.

Title Insurance & Trust Co., 1315197, low frequency system.

Peter E. Stogoff, 1343165, submarine radio system.

J. Harris Rogers and H. H. Lyon, 1220005, 1322622, buried-wire antennae.

J. Harris Rogers:
1315862, underwater antenna coil.
1316188, loop antenna.
1303750, 1349103, 1349104, specific forms of buried-wire antennae.

The following claims have been settled or withdrawn: American Telephone & Telegraph Co., Clapp-Eastham Co., De Forest Radio Telephone & Telegraph Co., Dubilier Condenser Co. (mica condenser patents).

The board recommends that an offer of settlement be made to the following claimants:

The Marconi Wireless Telegraph Co. of America, under letters patent of Lodge No. 609154, Fleming 803684, and the Marconi patent 763772.

The International Radio Telegraph Co. (National Electric Signaling Co.), under patents of Fessenden, Nos. 706742, reissue 12168, 706746, 706747, 727830, 753863, 1050441, and 1050728. (No instances of infringement have been found upon this claimant's patents 846081, 950781, 1158112, and 1182946.)

Dr. Louis Cohen on his patent 1123098.

Emil J. Simon on his patent 1253103.

Lowenstein Radio Co. upon its patents 1258423 and 1305816.

E. H. Armstrong on his patent 1113149.

John Firth on his patent 1018769.

National Electrical Supply Co. on its patent 1145966.

Sperry Gyroscope Co. on its patents 1287116 and 1362753.

H. M. Horton on his patents 1165412.

American Mechanical Improvement Co. on its patent 1238838.

Wireless Specialty Apparatus Co. on its patents 836531, 912613, 933263, and reissue 13798.

Settlements having been made with the American Telephone & Telegraph Co. and the Dubilier Condenser Co., no recommendation is made as to these claimants. R. A. Fessenden having failed to formally present his claim, no recommendation is made as to it.

Considering that the value of the respective inventions to the Government can not be ascertained from returns from commercial uses of the inventions, the Government's use having been largely noncommercial; that great difficulty exists in ascertaining whether in an individual case an apparatus has been put to use; that great divergence occurred in methods of purchase of apparatus; and that other circumstances lead to indefiniteness of any other method of approaching the problem of ascertaining the exact figures, it has been concluded that 15 per cent on the cost price comes as near to being a fair and accurate figure on which to base the board's calculations as can be reached. In applying this percentage it has not always been possible to ascertain what proportion of the cost price is directly assignable to radio apparatus per se, and the board has in doubtful cases often leaned in favor of allowance to the claimant where the records obtainable have not enabled it to segregate such items. In some cases the utmost investigation has not enabled the board to ascertain the exact construction of

apparatus and the board has had to proceed in such matters more or less by inference from surrounding circumstances. [fol. 2487] Note is taken in the accounting of the different terms of expiration of the several patents, of the diminutions in royalty due to the articles having been furnished by the claimant or its licensee, and an average period of three months has been allowed between the date of requisition of apparatus and their delivery in considering whether such apparatus comes within the terms of the accounting. The fixing of a reasonable compensation at 15 per cent where the patents involved have been fundamental has called for a lesser allowance under the authority of the Westinghouse, Dowegiac, and other cases,[1] where other elements enter in limiting the proportion, as, for example, the expiration of one or more of the fundamental patents, its conclusion in the cost price by reason of the article having been furnished by the patentee, or the necessity of apportioning a compensation between a number of claimants. In the case of apportionment of a total royalty regard has been had to the relative importance of the invention in the individual cases. Where the invention is not fundamental but has referred to an individual part or piece of apparatus used as an improvement on or substitution for a previously used device, a basis of compensation at the rate of 10 per cent has been allowed, with suitable apportionment, where several patents are concerned in the article; and in certain cases of minor importance the compensation has been limited to a less percentage. The board has not pretended to reach mathematical exactitude, nor does it consider this necessary. (Underwood Co. v. Stearns & Co., 227 Fed., 74.)

In subdividing the subjects matter of radio apparatus purchased it has been convenient to take them up under the following heads:

1. Complete transmitters and receivers.
2. Receivers.
3. Transmitters.
4. Detectors (crystal)
5. Arc transmitters.
6. Receiving tuners.
7. Vacuum tubes.

[1] See Garretson v. Clark (111 U. S., 120); Westinghouse v. Wagner (225 U. S., 604); Dowegiac Manufacturing Co. v. Minnesota Co. (235 U. S., 641); Dehoning v. Fox Typewriter Co. (251 Fed., 584).

8. Wave changers.
9. Wave meters.
10. Decremeters.
11. Quenched gaps.
12. Direction-finding apparatus.
13. Audion detectors.
14. Condensers.
15. Radio telephones.
16. Amplifiers.

As a rule no deductions have been made for patents owned by the Government or patents or inventions not before the board as claims. Departure from the rule has been made, however, in the case of the quenching-gap inventions. These inventions are of such importance in their relation to quenched-gap transmitters that it has not been thought reasonable to exclude them because several patents covering this feature came into the possession of the Government during the later part of the period of the accounting.

Another exception has been made in the case of the Poulson arc patents for similar reasons.

Complete transmitters and receivers.—The transmitters of these sets have been (1) with open-gap excitation, either fixed or rotary; (2) with quenched gap excitation; (3) with pure impulse excitation; (4) vacuum-tube excitation. (Arc transmitters and alternator transmitters are separately considered.)

The receivers of these sets have as a rule had two tuned circuits. Reference to the accounting sheets will indicate that each separate item constituting an order has been separately estimated with dissociation of the costs of the transmitter and receiver and with application of the several patents, first, to the transmitter; and second, to the receiver cost.

(1) *Open-gap transmitters.*—The foundation patents involved have been Lodge, Marconi, and Stone,[2] the basis being 15 per cent, 5 per cent each.

(2) *Quenched gap transmitters.*—The foundation patents involved are Lodge, for loading coil and impulse excitation; Marconi, for tuning and the quenching gap inventions, the basis being 10 per cent for the Marconi Co. patents and 5

[2] Loose coupling is for convenience identified with Stone's name, although no award is made here to owners of those patents.

per cent for quenching gap inventions. Specific allowances deducted from these sums, however, have been made for the Simon individual quenched gaps. (No Lowenstein type gaps are found in these sets.)

(3) *Pure impulse excitation.*—All patents before the board involved in this form of transmitter had expired before any purchases were made.

[fol. 2488] (4) *Vacuum-tube excitation.*—Only a few sets of this kind were found under this heading, and the compensation was distributed among the Fleming valve patent, the Deforest tube patents, the heterodyne patent, and the Lodge patent, the rates varying according to the uses to which the sets were put.

Receivers of complete transmitters and receivers.—The basis of arrangement is shown more fully when orders comprising receivers alone are reached, the only difference in this case being that the cost of receivers of these sets have been estimated where no information was available as to the cost of the receiver *per se*.

Receivers.—These are divided into three heads:

(1) Receivers arranged with terminals for any form of detector.

(2) Receivers having built-up accommodations for vacuum tubes (*a*) arranged for both oscillations and regeneration, or (*b*) arranged for oscillations only.

(3) Radio compass receivers.

(1) *Receivers arranged with terminals for any form of detector.*—The foundation patents are Lodge, Marconi, and Stone. Where the Lodge and Marconi patents are involved the full 15 per cent has been allowed to Marconi, diminished by 5 per cent for the Stone loose coupling patents when they were in question and diminished by a further 5 per cent on the expiration of the Lodge patent. Where mountings for crystal detectors were included, an amount of $1 per mounting has been deducted for the Wireless Specialty Apparatus Co.

In a few instances of statically coupled receivers of the Cohen type, an allowance was made the Cohen static coupling patent at the rate of 3.75 per cent. It has not been overlooked by the board in reaching this figure that a larger amount has in some instances been paid to Mr. Cohen by contractors—an amount based, in part at least, on en-

gineering services. A proper apportionment of credit has resulted in fixing the above percentage, and credit has been made in these few instances without disturbing allowances already made on these sets to other patentees.

(2) *Receivers having built-in accommodations for vacuum tubes.*—(*a*) Arranged both for oscillations and regeneration: The inventions involved were Lodge, Fleming, Marconi, Beforest tube and Stone loose coupling, the Armstrong regenerating circuit and the heterodyne, and allowance made (Lodge having expired) at the rate of 5 per cent for Marconi and 2½ per cent for each of the remaining claimants.

(*b*) Arranged for oscillations only: The patents involved are Fleming, Marconi, Deforest, Stone, and heterodyne. On account of the relative importance of the heterodyne invention in these sets, the allowance has been at the rate of 4 per cent for Marconi and Fleming patents, 4 per cent for the Deforest and Stone patents, and 4 per cent for the heterodyne patents.

These are the main subdivisions. Still other somewhat different forms are found in which some variation has been made, depending upon the arrangement of the structure and the use to which it is put.

Transmitters.—There are (1) spark transmitters (open gap); (2) quenched gap transmitters; (3) vacuum-tube transmitters; (4) buzzer transmitters. The apportionments of royalties are the same as in transmitters of complete transmitters and receivers.

Detectors (crystal).—Allowance for the crystals themselves and their mountings has been made at the cost or estimated cost price thereof at the rate of 10 per cent to the Wireless Specialty Apparatus Co., where their patents were involved.

Arc transmitters.—These have included stations in which long waves were employed and those in which short waves were employed, and the patents involved are the Fessenden long wave, the Fessenden inductance shunt key, the Fessenden heterodyne patents, the Lodge patent, and the Poulsen arc patent, with an allowance of 7½ per cent, as a rule, to the International Radio Telegraph Co., 2½ per cent to Marconi Co., and 5 per cent to the Poulsen patent. In cases omitting the inductance shunt key the allowance to

the International Radio Telegraph Co. has been reduced to 5 per cent. In the case of the New Brunswick station allowance was made at the rate of 10 per cent to the International Radio Telegraph Co., based on the amount paid for the maintenance of the station during the Government occupancy. No allowance has been made for the Tuckerton Station, this matter being in litigation.

In the accounting no reference is made to the Bordeaux (Lafayette) Station, erected by the Government on French soil, with radio material furnished from this country, under the doctrine of Bullock *v.* Westinghouse (63 C. C. A., 607). Furthermore, this station was not completed during the time of this accounting.

[fol. 2489] *Vacuum tubes.*—The equal rate of 5 per cent has been allowed to the Fleming valve and the Deforest patents, following the rule which was generally adopted of allowing a total compensation of 10 per cent where the patents related to an individual part of the apparatus rather than to the whole system.

Wave changers.—The only patents involved are the Lodge and Marconi patents, and the allowance varied from 5 to 15 per cent, depending upon the use of quenched gap and the period of purchase. The device itself is not an infringement, but allowance has been made on the assumption that these wave changers were purchased for incorporation in sets involving one or both of these patents.

Wave meters.—Allowance has been made at the rate of 10 per cent of the cost of detectors for the Wireless Specialty Apparatus Co. and 10 per cent of the cost of the condensers for the Lowenstein Co. (where the condenser is logarithmic type) and at the rate of 5 per cent of the total in the case of special wave meters involving the heterodyne patents. On the special uni-polar detectors of the Midgley type an allowance of 7½ per cent has been made to the Midgely patent.

Decremeters.—An allowance of 10 per cent of the cost of the condensers per se of a decremeter has been made for Lowenstein's logarithmic condenser patent.

Quenched gaps.—These have been bought as replacements of other gaps, and it is not considered that compensation on the system patents should be allowed. Where the Simon gap has been used allowance has as a rule been made to Simon at the rate of $10 less depreciation where the purchase has occurred before the date of his patent, but where

the individual units have been purchased the allowance has been at the rate of 5 per cent of the cost. In one instance in which the set was furnished with the Lowenstein switch allowance has been made to Lowenstein at the rate of $10 per set less depreciation for purchase prior to grant of his patent. Such gaps have averaged $200 each purchase price.

Direction finding device.—Where the patents involved were Fleming, Deforest, Armstrong, and heterodyne, $3^3/_4$ per cent has been allowed to each claimant.

Audion detector and Audion control boxes.—Allowance of 5 per cent has been made to Marconi for the Fleming patent and 5 per cent to the Deforest patents, except in one instance in which tickler coils were used, when the allowance has been at the rate of $3^3/_4$ per cent to Marconi for the Fleming patent, $3^3/_4$ per cent to Armstrong, $3^3/_4$ per cent to the heterodyne patent, and $3^3/_4$ per cent to the Deforest patents.

Condensers.—An allowance to Lowenstein is made in the instances in which his logarithmic condenser invention is employed at the rate of 10 per cent less depreciation prior to the grant of his patent.

Radio telephones.—The patents involved were Fleming, both transmitter and receiver as a rule, the Fessenden telephone patents, the Armstrong regenerating circuit, and the Deforest patents. The allowances have varied according to the importance of the patents to the set, being in the main at the rate of 6 per cent to Marconi, 3 per cent to the International Radio Telegraph Co., and 3 per cent for the Deforest patents at the receiver, and $3^3/_4$ per cent to each of these claimants at the transmitter, the allowance to Armstrong varying from 2 to $2^1/_2$ per cent where his invention was involved, with corresponding reduction of the other allowances in these cases.

Amplifiers.—The allowance has been at the rate of 5 per cent for the Fleming patent and 5 per cent for the Deforest patents, no allowance, however, having been made for the Fleming patent for vacuum tube amplifiers constructed for purely low frequency or "TPS" conductive signaling.

Receiving tuners-variometers.—Allowance is made to the Marconi Co. at the rate of 5 per cent for the Marconi tuning patent.

Heterodyne method.—The allowance for primary radio stations is fixed to average $2,000 per station, and for

secondary radio stations $500 per station under the heterodyne method patent of the International Co.

Arco fans.—An allowance of 10 per cent has been given where such fans fall within the terms of Slate patent 1,238,838. The Sperry patents have been made the subject of a special recommendation for a part and future license for a fixed sum.

Airplane radio.—The Horton patent has been made the subject of a special recommendation for a past and future license for a fixed sum.

[fol. 2490] The complete list of apparatus taken from Government records by the accountants is shown in the sheets filed among the board's records and not attached to this report. Tables estimating the compensation due the several claimants as estimated by the board on each order are annexed thereto.

The total amount due from the Government to patent owners is found by the board to be $2,869,700.27, apportioned as follows: By the Army, $1,050,179.58; by the Navy, $1,819,520.69; total, $2,869,700.27, and divided among the claimants as follows:

Marconi Wireless Telegraph Co. of America	$1,253,389.02
Wireless Specialty Apparatus Co.	[3]22,449.69
American Telephone & Telegraph Co.	615,333.57
Sperry Gyroscope Co.	5,000.00
E. H. Armstrong	89,624.74
E. J. Simon	30,273.31
International Radio Telegraph Co.	711,451.85
H. M. Horton	75,000.00
Lowenstein Radio Co.	22,892.80
National Electrical Supply Co.	8,875.00
Dubilier Condenser Co.	18,194.31
American Mechanical Improvement Co.	383.80
Louis Cohen	1,271.25
John Firth	15,560.93

The claims of the American Telephone & Telegraph Co. and the Dubilier Condenser Co., so far as included in the above amounts, have been waived or released to the Government under agreements between the claimant and the United States recently consummated, leaving as the net

[3] Determination not yet final.

amount of the total of the claims considered valid and outstanding $2,236,172.39, of which the Army's pro rata is $658,871.11 and the Navy's pro rata is $1,577,301.28.

Precept

[Paper A]

Whereas the operations of the War Department and the Navy Department during the war relating to the furnishing of adequate supplies for radio communication developed the fact that the patent rights of greatly needed supplies were diversely held, which rendered quantity production by the employment of all of the available manufacturing facilities difficult, which situation made obvious the necessity for proceeding with production without regard to the existence of patent rights, orders for which procedure were issued by both departments, wherein the United States Government directly assumed responsibility for the proper compensation for the unauthorized use of patent rights; and

Whereas large claims were presented to the United States, flowing out of such procedure, in addition to others which already had accumulated and for which suits had been filed against the United States in the Court of Claims; and

Whereas the situation thus produced made obvious the advisability of creating a board of experts in patent law and radio science for the purpose of determining scientifically the measure of liability in which the Government became involved; and

Whereas the Secretary of War suggested the creation of such a board to the Secretary of the Navy and the Attorney General, in which suggestion they concurred and out of which was created by separate appointment representatives of the Secretary of War, the Secretary of the Navy, and the Attorney General, to constitute the interdepartmental Radio Board, which board has been heretofore organized and has made considerable progress in the discharge of the duties the problem presented seemed to require.

Now, therefore, it is directed that the officers and representatives of the several departments heretofore appointed, to wit, Commander Stanford C. Hooper, United States

Navy, and Lieut. Commander Edward H. Loftin, United States Navy, representing the Navy Department; Capt. Guy Hill, United States Army, and Robert H. Young, Esq., representing the War Department; Harry E. Knight, Esq., representing the Department of Justice; and any successors [fol. 2491] of any of said members who shall hereafter be, from time to time, appointed shall continue as a board, designated the Interdepartmental Radio Board, to investigate, hear, and examine the questions relating to the liability involved in the use by the Government of patents on radio apparatus and similar devices and render to the several heads of the departments mentioned their conclusions and recommendations therein.

Such assistance and information as the board may require will be rendered to it by the officers of the respective departments familiar with patent and technical matters involved in those departments.

Newton D. Baker, *Secretary of War.* Josephus Daniels, *Secretary of the Navy.* A. Mitchell Palmer, *Attorney General.*

To the Interdepartmental Radio Board,
Navy Building, Washington, D. C.

Washington, D. C., *February 12, 1921.*

Mr. Garrett: What do you mean by a patent-holding concern? Is that a concern which simply holds the patent rights and does nothing else, and is seeking to get certain awards?

Commander Loftin: It is a straight out exploiting of patents—selling licenses for patents.

Mr. Garrett: And the only investment they have is the patent itself?

Commander Loftin: We have not many of those to deal with; but sometimes capital will financially back an inventor, and it takes money to do that. They equip laboratories and sometimes arrive at something that is valuable.

Mr. Garrett: What you mean by a patent holding concern is one that includes the original patentee with his financial backers—that is, he usually takes in a lot of people with him and they finance his project? Usually an inventor is a rather poor fellow and has not much money, and he gets some people to go in with him, and they put the patent on the market.

Commander Loftin. The Vreeland Apparatus Co. is the only company of that kind that we have a claim from. They may make a small amount of apparatus, but they do not make any radio apparatus. We have a number of individuals, of course, who have made inventions themselves.

Mr. Wright: Under the war power the Navy Department had the right to use any of these patents, even without the consent of the patentee?

Commander Loftin: Without the war power we have always had it, and it was not until the passage of the act of 1910 that we have had to pay for those things.

Mr. Wright: It is because of the use of these patents that these claims have been made?

Commander Loftin: Yes, sir.

Mr. Garrett: You say prior to 1910 the Government did not have to pay for them?

Commander Loftin: No, sir; the inventor had no way of reaching the Government, up to 1910, for the use of his invention. The act of 1910 gave him the right to make a claim in the Court of Claims, and the act of 1918 modified that act so that the Government takes all the liability; the [fol. 2492] contractor does not take any liability, as I understand the act, so that from now on we have to watch our step and take care of inventors.

Mr. Wright: You mean that up to the time of the war the Government could use any patent without the consent of the patentee?

Commander Loftin: That simply means the patentee can not enjoin the Government from using it.

Mr. Wright: You have compensated him?

Commander Loftin: We have recommended compensation where we have done that.

Mr. Garrett: Before that the Government exercised its function as a sovereign and did not concede that, having granted a patent to one of its citizens, the citizen possessed a greater right than the Government possessed when it wanted to use a patent for its own purposes?

Commander Loftin: There has been no provision made for it. The only way an inventor could make any claim at all was where the Government in some way implied or made a contract.

The Chairman: Is there anything further you desire to present to the committee?

Commander Loftin: There is one other point I would like to make as to the practical effect of what this board has been doing. We supplied thousands of ships of the Shipping Board with radio apparatus. The Shipping Board does not know that a patent situation exists in radio apparatus. They have had one or two letters from people who did not know that this board was functioning. So through this board we have allowed the Shipping Board to go ahead undisturbed in this complicated field of patents without knowledge of or interference from patent owners. They have all been coming to us.

If there had not been such a board as this, the Shipping Board would have been swamped with claims from the different patentees. I think they would have gotten to a point where they would have been glad to have thrown the apparatus overboard rather than to have used it under the annoyances they would have had if we had not been handling the situation for them.

I have recently had occasion to talk to some of those people about this general situation, and they thoroughly appreciate what has been accomplished for them. They know there is such a situation, but they have never felt its full purport.

Another point as to the seriousness of this proposition. Admiral Griffin, who is the chief of the Bureau of Engineering of the Navy Department, was greatly disturbed about this situation all through 1918, in the middle of the war, and I was in France at that time very much occupied in the development of the high-power radio system we were arranging for in case the cables were cut and we should be denied communication by that means.

It was very important work, and there were many details to be arranged with the British and French as to a real working communication system to take the place of the cables.

I was one of the few officers who had the advantage of having had a postgraduate course in this particular art, and Admiral Griffin desired that I should come back and take up this patent situation, and he made many urgent requests prior to the signing of the armistice for my release from [fol. 2493] the other side, but that was not approved by Admiral Sims on the other side because of the urgency of that work until after the signing of the armistice. I merely mention that to show that a man as busy as Admiral Griffin

was during the war had this on his mind, deeply imbedded in his mind, to the extent of trying to interfere with Admiral Sims's organization on the other side at a very crucial moment.

Mr. Parker: You say some of these patents, what they call pioneer patents—some patents are merely subsidiary patents; is that not so? I mean that the pioneer patent for radio communication was claimed by Marconi, was it not?

Commander Loftin: Yes, sir; we had that one before us.

Mr. Parker: Were there any conflicting claims for the basic patent between the Deforest and the Marconi Cos.?

Commander Loftin: No, sir.

Mr. Parker: I remember at the beginning of the war there was a great deal of trouble because the Deforest Co. wanted to stop our use of radio altogether.

Commander Loftin: The Marconi Co. has sued the Deforest Co. two or three times for use of the early Marconi patent and the second Marconi patent, which is well known in the art, and several others.

Mr. Parker: I am glad to hear that the Deforest Co. does not claim the basic patent, as against Marconi.

Commander Loftin: Not as to a wireless system. Deforest made a very important invention in what is known as an amplifier, the little vacuum tube which they use with the receivers, which has proved of such great value in intensifying the weak signals, allowing a certain amount of power to reach a much greater distance because of the greater strength at the receiving end.

Mr. Parker: I wanted to get at this—whether the Deforest claims were such that if the Marconi claims were allowed, the Marconi Co. would guarantee us against the Deforest claims. You say they claim different things?

Commander Loftin: They have had a claim on this particular tube. Both of them have very important patents in that particular tube, but they have no conflicting claims on a wireless system.

Mr. Parker: Have they conflicting claims on this vacuum tube?

Commander Loftin: They do not conflict; they are specific inventions which are easily separated.

Mr. Parker: Do they claim that either one infringes the other?

Commander Loftin: The Marconi Co. claims that the patent on the tube which involves the Deforrest invention

infringes the patent which they own, and the courts have so held.

Mr. Parker: In that particular case, as to that particular article, ought we not to receive from the Marconi Co. as a part of their settlement, a guaranty against claims of the other company on that device?

Commander Loftin: It so happens in connection with that particular device that during the period when Deforest had a claim, without any legal question, he made all those devices. The Marconi Co. has a claim for those devices, but Deforest has not; he having furnished them, he has no claim, but the Marconi Co. has a claim. During the war, [fol. 2494] which was after the time when the Deforest Co. transferred such rights to the American Telephone & Telegraph Co., there was grave doubt as to whether or not it (Deforest Co.) had any legal claim.

Mr. Parker: I understood that. The question I put to you, which you have not answered, is whether it ought not to be a part of the Marconi release that they guarantee us against a claim by the Deforest company for things that are identical with the things they gave us?

Commander Loftin: There will be no claim by the Deforest company, because they made the apparatus and the license goes with the sale of it.

Mr. Parker: To the United States?

Commander Loftin: To the United States.

Mr. Garrett: Where we are buying them outright it is simply a question of settlement with them for their original apparatus that they invented themselves?

Commander Loftin: The license goes with the sale.

The Chairman: Commander, do you speak for the members of the board from the other departments in this matter?

Commander Loftin: No, sir; I have been chosen by my coworkers on the board as chairman of the board.

The Chairman: Are the other members of the board here to be heard?

Commander Loftin: They are here, and I will be glad to have them asked to verify anything I have said; they may think what I have said is a little bit off in some respects.

The Chairman: We will be very glad to hear from your coworkers.

Statement of Mr. Harry E. Knight, Special Assistant to the Attorney General of the United States, Delegated to Represent Him on the Interdepartmental Radio Board.

Mr. Knight: Mr. Chairman and gentlemen of the committee, the questions of some of the members of the committee have indicated the possibility of a lack of full knowledge on the part of some as to the history of these litigations in which the Government may be involved.

The Government, of course, being sovereign, can only be sued by its own consent. After a long consideration of the matter, the Government consented to be sued in certain cases, and the Tucker Act was passed, which enabled the Government to be attacked under a contract. For a long time the question of litigation against the Government in matters involving tort was subject to much controversy. Actions were brought directly against the Government and dismissed because being laid in tort; the Government being claimed by the claimants to have proceeded without right from the claimant, but against his rights, those actions were dismissed as being not properly covered by the law.

There was very considerable doubt often on those points, and there is one very early case of that kind in the Supreme Court of the United States, in which one of our leading ju- [fol. 2495] tices dissented strongly from the opinion of the Supreme Court, saying he considered that the grant of a patent by the Government and the use of the invention covered by that patent by the Government implied a contract, and he would recommend that the Supreme Court proceed with judgment in favor of the patentee in case the patent were sustained, and as if it had been used on an implied contract. That, however, never became the ruling of the Supreme Court.

Other cases were brought against officers of the War Department or other departments trying to stop their use of a thing for the Government, but on the supposition that they might be reached as individuals. Thus in some cases the article was an invention which was used for the Government, and the people using it were working as officers of the Government. There was, however, the conclusion reached that these officers could be prevented from future acts by injunction, but the Government could not be interfered with in the use of material that it had purchased or

constructed, but the officers could be restricted from further infringement.

That caused a good deal of commotion among patentees, and finally the act of June 25, 1910, was passed, in which a right was given against the Government direct in favor of a patentee when the Government had, without license or authority of the patentee, used the invention. There was no expression in the act which excluded action also against the contractor with the Government.

It was quite a general opinion that the effect of this act was to make the Government a licensee, so that a contractor with the Government would be free, for if he were dealing with a licensee he could not be attacked. It was the general opinion at that time that the Government had appropriated a license. Contractors during the war went largely on that hypothesis, that by the act of June 25, 1910, they were protected. They were dealing with a licensee, and the Supreme Court had used expressions which indicated that. They went ahead and continued to contract with the Government as they had in the past, warranting the Government against any suit of all other patentees. In 1918, however, the Supreme Court rendered two decision, which entirely changed the view of patentees and other persons. Those were the cases of Cramp and Simon. The result of those, briefly, was that while the Government could be sued a contractor could also be sued, unless, as found in the Simon case, there were such relations as to make the contractor a mere contributory infringer. In other words, the Government was the real infringer and should have been the one primarily attacked.

Before that time, and fearing that that might be the outcome of the suits, various contractors of the Government, and the Deforest Co. was one of them, had represented to the Secretary of War the dangers that they were getting into by these large orders given out by the Government, and their warranties that were given to protect them against an unknown situation, because radio patents, being a new art, were coming out constantly. There were hundreds of applications in the Patent Office and thousands of patents were being issued. The contractors became very nervous and they asked that they should be relieved of this situation, and that the Government should assume the burden of it. The Government then assumed a different attitude in mak-

ing its contracts. The Government was at war and did not [fol. 2496] want its contracts held up, didn't feel that it could seize all these factories and have its matters held up; it wanted the individual initiative and help of the factories. So it began itself to assume the responsibility and warrant the contractor, and then came along the act of 1918 and made the Government the sole infringer and relieved the contractor.

Before the war started, the situation in radio patents begun to be somewhat distinct from that of patents generally. Of course, in a country like this which depends so largely on industrial progress and has given so much favor to its patent system, all the different devices which had been used by the Government had been affected by patents, and had been for years affected by them. But radio was a different situation. It was practically a new art, Marconi's early experimenting was in 1895, some 25 years ago, and his fundamental patents have only recently run out. Indeed, one that he has claimed as fundamental only runs out this year.

Here is a situation that presented a constant development on a great many different lines, interweaving lines, lines which if they had been sent to a court would have necessarily been taken up by piecemeal. Take for instance one of the cases cited by one of you gentlemen. If Marconi had attacked one of these contractors in southern New York district and Deforest had attacked along the same line another contractor in the State of New Jersey, and so on throughout the United States. Of course the courts give a good deal of leeway to the Department of Justice in defending the Government in such cases where the rights have been so split up, but inevitably even if sufficient time had been given the Government to defend all these litigations, we should have had before we got through hundreds of accountings, and with the difficulty that each accounting would have taken very little cognizance of what had taken place before. Accounting is a very technical thing, and it is handled along a very unusual way.

There was a case recently in New York where a suit had been brought under three different patents—two claimants, three patents—three claimants against one victim, and the patents were sustained, and the case went to a master. Both cases were referred to ex-Judge Lacombe, a judge who has had tremendous experience in this class of litigation. He

was appointed to hear and determine the case. He reached a basis of accounting which went in two or three very peculiar directions, but he worked it out very thoroughly and then it was brought before a court, and the way he reached his conclusions—and his conclusions were all attacked—and without entering at all into the merits of the case (the matter is still subject to judicial determination).

Judge Mayer has used a very different method from that that was reached by Judge Lacombe. Different judges have very different views of what should be done on accountings, and back of all that is the question of what a patent really means. We find, for instance, in Marconi's four circuit toning patent an entirely different decision reached in the second circuit from that reached in the far western coast circuit. So that if this had gone up, we should have encountered numerous accountings and copending cases. And this is much more difficult because of the unusual number of claims pending. There had been brought in 1918 a large number of claims, but we knew that there [fol. 2497] would be many more, because patents were issuing constantly. We have had brought before this board patents that were of very recent issue. So that the principal claimants, the Marconi Co. and the Deforest Co. and the International Radio-Telegraph Co., all urging their claims before the War Department, agreed that the matter might be referred to some joint conference of representatives of the War, the Navy, and the Justice Departments, they being the principal ones concerned, to see whether some satisfactory result could not be reached without litigation. They all had their claims that they could present through the Court of Claims and all through the country in the district courts. But they were willing to submit their claims to a board, and I must say that these patentees and these concerns interested with the patentees, have shown throughout a most conciliatory attitude toward the Government. In nearly all instances there has been no disposition shown to press the Government unduly, or take any advantage of it, or to ask for an unreasonable amount.

The Chairman: There has not been a case of gouging.

Mr. Knight: In no case whatever has there been any gouging or any attempt at it.

So, members of the War Department, the Navy Departmentment, and the Department of Justice came together

and called themselves the interdepartmental board, just to have a name to do business with, and to forestall future controversies they sent notices to every one who might have a claim.

The Chairman: Have you a copy of that notice?

Mr. Knight: Yes, sir. It is among the papers here.

The Chairman: Will you kindly give it to the reporter.

Mr. Knight: I think the chairman intends to file all of those papers.

The Chairman: Very well.

Mr. Knight: A number of them responded.

The Chairman: You need not take the time now, Mr. Knight. You can give it to the reporter afterwards.

(The notice referred to is as follows:)

February 12, 1919.

SIR: The board considering the claims of owners of patents for radio inventions asserted to have been used by the Government has been referred to so large a number of patents that unless the field of investigation be narrowed materially the work of the board will be greatly protracted and a satisfactory adjustment extremely difficult or impossible to reach.

Since it is the purpose of the board to expedite its work and reach a conclusion with the least possible delay, and this also being the desire of the patent owners concerned it has concluded to ask these patent owners to cooperate in reaching that object by giving due consideration and answers to the following questions in such manner as they think will render the most assistance to the board:

(*a*) What patents owned or controlled by you are basic adjudicated patents or are nonadjudicated patents that you consider are generally recognized as basic and which you regard as having been employed in standard practical apparatus that has been actually used by the Government? (Identify the patent or patents by number, date, name of patentee, and identify as definitely as practicable, the type of apparatus in which you consider said patents involved, and how involved.)

(*b*) If you should obtain a settlement based on the patents named in answer to (*a*), will you lump all other patents owned and controlled by you in that settlement without further claim for royalty on these other patents so lumped? [fol. 2498] (*c*) What patents owned or controlled by other

companies or individuals do you regard as basic adjudicated patents or as well-recognized basic nonajudicated patents that should be taken into account by the board in considering the general settlement of royalties? (Give name, number, and date of patents, by whom owner or controlled, type of apparatus in which said patents are involved, and how involved, so far as information on the subject will permit.)

The board is of the opinion that only by a response to the subject matter of the foregoing inquiries given in the most liberal spirit with due consideration for the patents and claims of others can it hope to arrive at any early conclusion or settlement of the matters involved and begs you to have these considerations well in mind and earnestly cooperate with the board toward reaching an early settlement.

Mr. Knight: A number made no answer. A number said they had no claims against the Government. Those were these: The Federal Telegraph Co., General Radio Co., Liberty Electric Corporation, Moorehead Laboratories (Inc.), American Radio & Research Corporation, Westinghouse Electric & Manufacturing Co., and Kilbourne & Clark Manufacturing Co. These companies all stated that they had no claim for infringement. There were 25 claimants, however, who put in claims for patents. Of these we refused to consider one because we didn't consider it radio at all, leaving 24.

(The papers referred to are as follows:)

February 12, 1919.

SIR: The board considering the claims of owners of patents for radio inventions asserted to have been used by the Government has been referred to so large a number of patents that unless the field of investigation be narrowed materially the work of the board will be greatly protracted and a satisfactory adjustment extremely difficult or impossible to reach.

Since it is the purpose of the board to expedite its work and reach a conclusion with the least possible delay, and this also being the desire of the patent owners concerned, it has concluded to ask these patent owners to cooperate in reaching that object by giving due consideration and answers to the following questions in such manner as they think will render the most assistance to the board:

(*a*) What patents owned or controlled by you are basic adjudicated patents, or are nonadjudicated patents that you consider are generally recognized as basic, and which you regard as having been employed in standard practical apparatus that has been actually used by the Government? (Identify the patent or patents by number, date, name of patentee, and identify as definitely as practicable the type of apparatus in which you consider said patents involved and how involved.)

(*b*) If you should obtain a settlement based on the patents named in answer to (*a*), will you lump all other patents owned and controlled by you in that settlement without further claim for royalty on these other patents so lumped?

(*c*) What patents owned or controlled by other companies or individuals do you regard as basic adjudicated patents or as well-recognized basic nonadjudicated patents that should be taken into account by the board in considering the general settlement of royalties? (Give name, number, and date of patents, by whom owned or controlled, type of apparatus in which said patents are involved, and how involved so far as information on the subject will permit.)

The board is of the opinion that only by a response to the subject matter of the foregoing inquiries given in the most liberal spirit, with due consideration for the patents and claims of others, can it hope to arrive at any early conclusion or settlement of the matters involved and begs you to have these considerations well in mind and earnestly cooperate with the board toward reaching an early settlement.

May 15, 1919.

Referring to your recent letters to the Interdepartmental Radio Board concerning the matter of claim for infringement of radio patents owned by you, the board now requires additional information, and requests that the following questions be answered at the earliest possible date:

(*a*) Have you granted any licenses, now expired or still existing, under the patents listed in your letter?

[fol. 2499] (*b*) Are the licenses of such a nature as to permit the licensee or sublicensees to manufacture and to sell to the Government for its use without royalty?

(*c*) Names of such licensees.

(*d*) Effective dates of such licenses (dates beginning and dates expiring).

(*e*) Are you a licensee under any patents owned by others, which license permitted you to manufacture and sell to the Government for its use (past and existing)?

(*f*) By whom granted?

(*g*) Effective dates of such licenses (dates beginning and dates expiring).

(*h*) Under what patents?

(*i*) Will you kindly furnish a copy of any license above referred to?

This information is necessary to the board in order to avoid making allotments on royalties to the wrong parties.

It is desired that the response shall be as of April 15, 1919.

Mr. Frothingham: You sent these notices to all the 25 claimants?

Mr. Knight: No, sir. We sent them to all that we supposed might make a claim.

Mr. Frothingham: And you thought there would be some likelihood of recovering if they went before the Court of Claims?

Mr. Knight: Yes, sir. I might say this, that those of us who have been devoting our consideratoin to this art have estimated, but only roughly, whom the principal patentees are. We know who the patentees are, of course. We know those who have patents of merit. For instance, no one would think of omitting the Marconi Co., or the Deforest Co., and so on. So we sent out this list and the result was that it was trimmed down to 24 claimants. And I would like briefly, if it please the committee, to revert to these several claimants, because it will bring this thing up to what it will result if settled in this way rather than by litigation.

The Chairman: The committee would be very glad to have you state that.

Mr. Knight: First, the Vreeland Apparatus Co. (we have these numbered just as they appear on our books, the order does not show when the claim started or the importance of the claim) made claim under four patents. Their cla m was one of very considerable difficulty. The Government was more or less involved by their claim. Most of you

remember that during the war the Atlantic Communication Co., representing in this country the German Wireless Corporation, was succeeded in this country by the custodian. Among its effects was found an agreement with the Vreeland Apparatus Co. for the use of its invention, and that was seized or bought by the Government custodian among other claims. It was considered by the Munitions Patent Board that that contract (the Government having taken this license over), that that license had lapsed on account of failing to continue to make payments for license fee. So the claimant came to our board to ascertain whether the patents were valid, whether the Government was bound to respect them by reason of this patent, or otherwise, and whether the Government had used the apparatus and the patents. Two of the patents concerned were subject to broad patents controlled by the International Radio Co.

I will not bother your committee by going over the months-long study by the board of the patents, but we reached the conclusion finally that the situation was not so clear that the committee could recommend the Government make any payment on this part of the claim. The remainder of the claim was under patents relating to oscillators. The patents had lain idle for a number of years, and were [fol. 2560] only brought up before our board as an afterthought, and we didn't feel under those circumstances that we should be the first to say that the Government should pay something for such patents, and we rejected the claim in toto, and it will go to the Court of Claims.

This is one case of a claim where the board was not able to settle. It was a claim so large under facts of such doubtful merit that we haven't thought it wise to prejudge before it goes to the court.

The next one on our list is the Marconi Wireless Telegraph Co. They have numerous patents, but they offered to waive all their claims if we made a satisfactory claim on a few, and they brought to our attention four as of particular merit. Those four patents are all fundamental.

They have all been sustained by the courts, and the Marconi Co. made very pointed representation to this board that they should have a special position because they were the only company holding claims that had been held to be fundamental, and they have all been sustained.

The Chairman: Lieut. Commander Lofton said that your board sustained three, and one had not been sustained.

Mr. Knight: Yes. I mean sustained by the courts. They had all been sustained by the courts. One was called the Marconi reissue patent, which is the fundamental patent for wireless telegraphy. The second was his improvement for tuning the two circuits at each end. The third was Lodge's patent for tuning the antennae and adjusting it by means of a coil. I speak of it in as simple terms as I can, because I imagine we are not all familiar with radio language. And the other was in connection with the Fleming patent, what is known as the Fleming valve. These were all important patents, but the first of them, while sustained by the court and held fundamental, had been held not infringed by the modern wireless systems. So we found no possibility of going beyond the courts in that, and we refused to allow the Marconi Co. on that. The other claims involved finding what the Government had done. They were evidently valid. They had been defended by various companies at enormous expense and held infringed.

(Thereupon a recess was taken until 2 o'clock p. m.)

After Recess

The committee met, pursuant to recess, at 2 o'clock p. m.

Statement of Mr. Harry E. Knight—Resumed

Mr. Knight: It has been suggested during the recess that in the Dent Act, to which this bill is proposed as an amendment, in order to avoid certain difficulties in the comptroller's office, who is the one man in the United States who must be obeyed by everybody, the words "on a fair and equitable basis" were inserted in the act after the words "to adjust, pay, and discharge," and the suggestion is that that addition be made to this bill also so as to prevent any too rigid interpretation by the comptroller of the actions of the heads of departments that are taken under this act.

Before taking up a little further in detail the various claims, I want to say one word about the number of the [fol. 2501] claims. I think, perhaps some confusion has been created in the minds of some members of the committee as to the number of claims. It has been stated there were some 2,500 patents.

The Chairman: Two thousand seven hundred.

Mr. Knight: Or perhaps 2,700. Each of these patents has what is called a number of claims in it so that there might have been brought before us, perhaps, 10,000 claims to separate elements of radio apparatus. A very large proportion of those patents, of course, have no relation to anything the Government or anybody else ever did, and I should say fully half of them nobody ever did anything with at all. Fifty per cent of all patents are merely unsuccessful dreams and probably the usual proportion of radio patents is the same. The committee has, however, examined all of these patents. Most of them it discarded from any further thought. Those that seemed to be important it has proceeded upon, and of those that were important, where it has received a claim on invitation, it has taken action on the claim, either favorably or adversely, except as to one or two cases not yet determined. After hearing from claimants, there were several hundred patents still before the board which the board had to consider of more or less importance.

Those were reduced, after much discussion, to about 150 patents, and by a further process of elimination, either by agreement with the claimant or by direct action of the board, those were all reduced to some 27 patents as the ones that were worth while passing upon at all. But with regard to the question of matters that may hang over, which has been the subject of some discussion here, the board is fully convinced that by this settlement, not only shall we save the Government much money, as to the details of which I think the Special Assistant to the Attorney General here, who is in charge of patent matters generally of the Government, can give the committee better information, but we shall have settled every claim capable of settlement either now present or which may become present on all of the activities of the Government in radio matters since the year 1910, which is the time of the beginning of any possible claims.

Mr. Hull: Right there, I thought you said this morning there were some claims not included in this settlement.

Mr. Knight: There are. Those are claims we have, with our best judgment, gone over and considered not capable of settlement; that is, not ready to settle, and they will have to go into court. I do not mean to say we have settled every claim on which suit may be or will be brought, but every-

thing on which we think a suit can justly be brought with a rendition of a verdict favorable to the claimant.

Mr. Hull: The Deforest people never came to you at all?

Mr. Knight: Yes, sir; we have had perhaps 25 arguments from them. Their claim has been in the Court of Claims since 1919.

Mr. Hull: You do not think they can justify their claim?

Mr. Knight: We do not. I do not mean to say in toto. They undoubtedly have a claim to some extent, but to the extent that they claim we were absolutely unable to reach an agreement with them. The question with some of these people is whether they have any claim at all. The question with others is, admitting they have some claim, how much can they justly be settled with, and where, for instance, with the Deforest Co. asking for $400,000 and we thinking [fol. 2502] the total sum they should have is $20,000, we are so far apart that we can not make a settlement with them. I do not instance those figures as the exact sums, but simply as an illustration.

The Chairman: But you contend that if they have any claim they can go to the Court of Claims and have that adjusted?

Mr. Knight: Yes. There is no attempt here to deprive a claimant of his rights in the Court of Claims. Our only attempt is to make settlements which will save the Government money and at the same time give these claimants their money within a reasonable space of time.

Mr. Hull: It is not exactly true that you have settled all claims?

Mr. Knight: No, sir.

The Chairman: Mr. Hull, they did not say this morning that they had done that.

Mr. Hull: No; but I understood him to say just now that this would practically settle all claims.

The Chairman: Except those of the Deforest people and one other company.

Mr. Knight: If I said that, then my language is incorrect.

Mr. Hull: Now, you say, "for all time." Let me clear that up in my own mind. You, of course, do not mean to say that you have settled a claim against the Government for an improvement that has not been made?

Mr. Knight: No; all claims that can be made for anything that has happened up to the date stated in the settlement.

Mr. Hull: Will this settlement give the Government the right to go ahead and use all these patents that we have settled for in this bill in the future?

Mr. Knight: In the future; and the bill provides that we shall have the right to do that, if possible. Of course, it is not always possible to make an arrangement for a future right. Sometimes the patentee is uncertain in his desires. He will want more than the Government is willing to give him, and the Government may finally say, "See us in the Court of Claims."

Mr. Hull: We are settling with the Marconi Co. under this bill?

Mr. Knight: Yes.

Mr. Hull: Does that give us the right to go ahead and use those patents in the future?

Mr. Knight: No, sir.

Mr. Hull: We have to pay for that in the future?

Mr. Knight: Yes, sir.

The Chairman: This only enables you to settle up to the time this agreement is finally acted upon by the President of the United States.

Mr. Morin: You have allowed for every case where there can be any substantial recovery made, have you not?

Mr. Knight: That is our judgment; yes. We have even gone so far, in some cases, as to allow something on account of the loss of the Government in litigation expenses; that is, we have had that in mind. It is a thing you can not reckon in exact figures, but it is always a thing we have had in mind. Where there is some doubt as to whether the claimant can sustain his patent, but we think the court may resolve those doubts in his favor, we have also had the fact [fol. 2503] in mind of the saving that the Government is making in litigation expenses.

Mr. Hull: Do you base your settlement on basic patents or do you base it on the service that the man rendered in getting up a new combination?

Mr. Knight: We have considered the size of the invention in its several aspects; the size so far as it may involve expensiveness of apparatus; its size so far as it relates to its position in the art. Where it is a very important patent we have paid much more regard to it, as we think the court

would, than to a less important patent. Indeed, our whole process of mind has been to try to find out, as far as we could, what the Court of Claims, which would be the tribunal hearing these cases against the Government, would do in the way of awarding fair and just compensation under the present acts of Congress.

Mr. Hull: They never award anything except for a basic patent.

Mr. Knight: Oh, yes.

Mr. Hull: They do?

Mr. Knight: Yes; wherever the Government has without right or license from the inventor used an invention, they make an award.

Mr. Hull: Whether he had a basic patent or not?

Mr. Knight: Yes, sir; the law of 1910 says nothing about basic patents. It says that wherever the United States has used an invention without right or license or authority, whatever the words are, from the inventor, etc.

Mr. Hull: As I understand it, and I may not be right about it, most patents are not basic at all, but are simply combinations of old principles.

Mr. Knight: You might almost say that all patents are combinations.

Mr. Hull: Not all; there are some basic patents, as I understand it. A manufacturer could manufacture any of those patents that are not basic, and the man who has the patent can not prevent the manufacture unless he has a basic patent.

Mr. Knight: No; that is not the law, sir. Within the limit of his right, the owner of a limited patent is as fully protected as the man who owns a patent as broad as the earth. The measurement is not of the quality of his right, but the extent of it.

The Chairman: And if anybody infringes that improvement of a basic patent, he is liable for that infringement?

Mr. Knight: Absolutely; if the owner of a basic patent should copy—supposing he is not merely a patent owner, but a manufacturer—Smith's patent for some little improvement and the court held, however small that improvement was, that it was still an invention, then the owner even of the basic patent will have to pay him.

Mr. Hull: But if the man could prove that the patent which he was copying was not fundamental, that it was

just simply an old principle applied, he certainly would have the right to use it.

Mr. Knight: No. It that goes to the extent of finding——

Mr. Hull (interposing): That is, as I understand patent law.

Mr. Knight: If it goes to the extent of finding that the patent is invalid on that account, yes; but a court can not find, first, that the patent is valid, however limited; second, that the defendant has used it, and still refuse to find the [fol. 2594] defendant guilty, and find him guilty in damages if they can be ascertained.

Mr. Hull: I do not understand why the Government should reimburse, unless it would be necessary, under the same circumstances, for a private corporation to do the same thing.

Mr. Knight: That is perfectly true; and there is no award that would be made without that.

Mr. Hull: Most manufacturers, or a great many of them, simply go and steal another man's patent right along, and if they have enough money they can get away with it, especially if it is against some poor fellow. They can do it right along, and they do do it.

Mr. Morin: Are you not doing the same thing that you would do with a private corporation?

Mr. Knight: Our findings, of course, are based on precisely the rulings that would be made against any corporation or any user of an invention.

Mr. Frothingham: You are acting under something that Congress passed in 1910.

Mr. Knight: Yes; in 1910 and 1918.

Mr. Frothingham: And it is up to Congress if anyone is to blame.

Mr. Hull: I think when that act or an act similar to that was passed I was not here; and they contended that the Government should reimburse the men holding the patent for the value of the improvement to the art, irrespective of whether he had a fundamental patent or not. I have always thought we should not do that. If a man, of course, has a fundamental patent, we are liable for damages. If he has not, I do not see how he can set up a claim for damages, because, as a matter of fact, when you examine the cases where the corporations have fought them out, the courts have ruled right along that unless a man can prove

he has a fundamental, basic patent he can not recover damages.

Mr. Knight: I think, perhaps, the cases you have in mind are those in which the courts have given less value to improvement patents.

Mr. Hull: I will cite the cases in reference to the internal-combustion engine—the Selden patents and all those cases.

Mr. Knight: That is a very good illustration. The Selden patent was held in the final decision by the court of appeals to be limited to a specific form of engine. It was held to be so limited a claim that the modern automobile had drifted away from it and the patent did not cover them. It was not held that because the patent was limited a defendant infringing it did not have to pay, but it was held that the defendant did not use it because the invention was so limited.

Mr. Hull: What he used was not an infringement; that is what they held.

Mr. Knight: Exactly.

Mr. Hull: That what he used was not an infringement because the principle was old.

Mr. Knight: Yes.

Mr. Hull: And that the patentee did not invent anything.

Mr. Knight: There is the distinction. You see the narrower you make the claim the less chance there is that the defendant will have used it; but however limited the claim, [fol. 2565] if the defendant has used it, then there has never been a decision that he does not have to pay for it.

Mr. Hull: But the claims of a lawyer in getting a patent are always very broad. He makes them as broad as he possibly can.

The Chairman: The basic patent is not always the most important. You will remember that the steam engine was a very valuable basic patent. Then George Westinghouse came along and patented a little airbrake, which made it possible to run that train at an enormous rate of speed. He became very rich. His patent was a comparatively simple thing, and yet that patent was as valuable, if not more valuable, than the basic patent.

Mr. Knight: This question of basic patents is largely an unprofitable one for discussion, because a basic patent may be basic for a few minutes and then is set aside by another basic patent. We had an instance of that in this art. For example, Fessenden had made his very valuable and very clever improvements in electrolytic detectors, which he

called a liquid barator. It was thought to be the only thing that was a substitute for the old forms of insensitive and difficult working detectors.

Mr. Hull: I do not want to go into a discussion of the basic patents and all that. I am not lawyer enough to do that. The point that I want to get at is this: In the settlement of these claims are we paying for patents or supposed-to-be patents, which they claim are patents, but they are not really patents, but they are registered and all that? I am pretty sure, if I remember aright, that Secretary of War Baker argued that we should do that; if anybody improved anything and had spent his time on it, we should pay for it—that is, if he had patented anything that could be sustained in the courts.

Mr. Knight: We have examined to see whether he had a valid patent, and then we have examined to see how broad that patent was, what its scope was, and we have tried to find out how many and what apparatus the Government had made which were under patent. That gave us some basis of estimating what payment should be made. If we thought the patent invalid or insignificant, that the improvement was not worth paying for, we have so declared; but if it was a substantial improvement and the Government used it and had the advantage of the invention and it was a legal claim which the Court of Claims would allow, we have, in that case, favored the claim.

Mr. Hull: That is all.

Mr. Wright: As to the Marconi patent, just how did you arrive at what was the proper amount of award to give for the right to make?

Mr. Knight: A wireless set has two very well-defined things. We have the transmitting end and the receiving end. There may be one transmitter and a number of receivers. Some inventions are peculiar to the transmitter and some to the receiver. Also, there are fundamental patents to each that go to the entire structure and some that simply deal with parts of the structure. You take, for instance, an ordinary radio installation and take the Marconi 4-circuit tuning patent. Marconi, before this other invention came up, had devised radio telegraphy. He now removed the spark gap, the device that put the oscillations into the vertical wire, from the vertical wire and put them in a side circuit and then tuned those two circuits together, [fol. 2506] so that the power would be efficiently trans-

mitted from one to the other. Of course, you can tune two electric wires just the same as you can tune two wires in a piano, so that when you touch one the other one responds. He took a patent for that.

We had to consider how much of those were used in our transmitters and how much were used in our receivers, and then we had to find out what other inventions were in it, because there were other inventions also that related to the entire transmitting set and some that related to parts of the set. The Court of Claims has been somewhat arbitrary in its fixing of awards that should be made to inventors. In ordinary cases against a private individual or corporation the court ascertains the entire profit that has been made by the defendant or the entire loss that has been suffered by the plaintiff or the damage that may have been caused to the plaintiff, finds out the biggest figure and gives it to the patentee. This board does not proceed exactly on that basis. It is not a question of damage to the plaintiff or what profit—the Government makes no profit. The law says that the court shall investigate and determine what shall be due and proper compensation. The law does not use the word "damages" nor "profits." Proceeding on that basis the board investigated and took testimony to ascertain what would be a fair amount.

We went on the basis that the general run of Government contracts during the war were made on a cost-plus 15 per cent basis. As a rule, the courts, outside of the Court of Claims, when they determine the amount that shall be awarded for profit, allow the whole profit, to go to the inventor unless there is some particular reason for diminishing it. In this case we had a number of reasons for diminishing it. We had a number of other awards to consider. Taking the total profit to the contractor dealing with the Government at 15 per cent on his cost price we had to fix a sum that we could deal with for dividing among these patentees. Having found, say, that such and such a set would have cost the Government a million dollars and that the profit on it was, say, $150,000, and the patents to be considered were Marconi's 4-circuit tuning, telephony patents, and so on, then we determined the relative value of these patents in the set. It varied some in different sets. In some sets the principal part of the thing would be the heterodyne, in others the principal object was to use it for

telephony, and so on, and so we had to give different weights to different patents at different times.

The Chairman: What does heterodyne mean?

Mr. Knight: What is ordinarily meant in music by beats. That is a very interesting patent. They had long desired to use in wireless what is known as the continuous wave, but when a continuous wave came over there was no means of receiving it unless you had some mechanical or other interrupter, and thus you lost a lot of the energy. Prof. Fessenden solved the problem by working with these high-frequency electric waves, so that if you were sending at 100,000 frequency per second and you put in your local circuit, going over the same wire, say 99,000 per second, then you would have traveling on this wire those two frequencies, one of 100,000 oscillations and one of 99,000, and the differences between the two, namely, 1,000, would be the frequency heard over the telephone. That is just about the [fol. 2507] natural frequency of the telephone diaphragm. He got a broad patent for that. In many of the systems used by the Government that is a very important means of receiving. In a great many of these cases, where it was so important for receiving the continuous wave, we have allowed a larger proportion to the heterodyne. In other cases, where the principal object was to use it for the telephone, we have allowed the telephone patent a greater weight. They have all had to split up the 15 per cent between them, because that is the limit we have been willing to go.

Mr. Hull: Fifteen per cent of the cost of the article?

Mr. Knight: Yes, sir; of the cost to the Government.

After all, the courts have always said that when it comes to these questions we must do a lot of guessing. We have exercised the privilege of the court in guessing once in a while. We have sometimes had to guess what the article was that the Government used. We have taken the best evidence we could get. We have pulled up sailors, officers, soldiers, and everybody else to try to find what this particular thing was, and we have found it.

The Chairman: Is it 15 per cent of the amount that the company or the corporation or the individual has put in a claim for?

Mr. Knight: Where the Government has bought an installation, say, for $100, we have estimated $15 of that was

profit to the contractor, and an amount similar to the profit to the contractor has to be divided between the inventors whose inventions he used.

The Chairman: That is exactly in line with what Mr. Hull suggested.

Mr. Knight: We have not always done that, because in some cases we have found that the prior art, as it is called—that is, the old art that everybody has a right to use—should receive its share. Thus the Marconi Co. was very much troubled because, having allowed them a percentage during the period of the life of the Lodge patent to their profit, we continued to take off that same percentage, but to the profit of the Government, after the Lodge patent expired.

The Chairman: It has been very interesting and we thank you very much.

Statement of Capt. Guy Hill, Officer in Charge of Radio Development Section, Office of the Chief Signal Officer of the Army, and Member of the Inter-Departmental Radio Board.

Capt. Hill: The problems of the War Department in radio are very similar to those of the Navy Department, except, of course, our work is different in not having practically any ship radio. We have aircraft, tanks, and a large number of portable sets for the Army. The inventions that have been used in the War Department apparatus are practically identical with the inventions that have been used in the Navy Department apparatus, except that we have not used them to as great an extent.

I think Commander Loftin, Commander Hooper, and Mr. Knight have summed up the work of the board and the way that the board has used these patents, so I have not anything definite to add, unless you have some specific questions.

[fol. 2508] The Chairman: You have heard their statements?

Capt. Hill: Yes, sir; I have been here all during the hearing.

The Chairman: And you concur in their findings?

Capt. Hill: I concur in the findings and in the statements which they have made before the committee.

Mr. Wright: You also concur in the statement that there has been a great deal of detail involved in the board's investigations?

Capt. Hill: I certainly do.

The Chairman: Is there any member of the committee who would like to ask any questions? [After a pause.] If not, we thank you very much.

Capt. Hill: I should also add, Mr. Chairman, that Maj. Young, the other member of this board from the War Department, is in full accord with the statements of Commander Hooper, Commander Loftin, and Mr. Knight.

The Chairman: I understand that he has been called away on account of the death of a member of his family. Otherwise he would have been glad to have been here and give his evidence along the same line?

Capt. Hill: Yes, sir. He was here a while this morning, but had to leave.

The Chairman: We are much obliged to you.

Statement of Mr. Edward G. Curtis, Special Assistant to the Attorney General, in Charge of the Defense of the United States in Patent Litigation.

The Chairman: How long have you held your present position, Mr. Curtis?

Mr. Curtis: Two years, Mr. Chairman, approximately. In that connection, with your permission, I might state how I came to be connected with the Department of Justice, and what my work has been there, so you may understand exactly the basis on which I found the statements that follow.

The Chairman: We shall be glad to hear you.

Mr. Curtis: Following my return from military service I was asked to come to Washington by Attorney General Palmer, to take charge of the defense of the United States in its patent cases.

A great number of patent cases against the Government had accumulated not only under radio patents, but under a great many other patents, and the Department of Justice at that time was not prepared to meet the situation. I came here and formed a department of patent defense, which consists of some 20 or 25 patent attorneys.

During these past two years I have participated in no less than 100 different pieces of litigation involving alleged

infringement of patents by the United States. In the course of these two years I have come into intimate contact with every branch of the departments of the Government which has any particular interest in or dealing with patent matters. Now, there is a foundation for the few remarks I have to make.

First, something has been omitted from the testimony given before you. The modesty of the members of the board [2509] has prevented them from saying what I can. I have watched the board from what might be called an outside position. They have worked with a high degree of intelligence and skill with this very difficult problem, and when they say, without any explanation, that the patent claimants have been docile, be assured the reason for it is that claimant after claimant has been obliged to concede the care and efficiency with which this board has examined the problems before them.

Speaking for the Department of Justice, I am impressed with the business aspect of the situation. It would cost the Department of Justice probably no less than $500,000 in counsel fees, expert fees, and other expenses to fight through the courts these various claims that this board has succeeded in getting to this point of settlement.

Secondly, I have no doubt whatever that should the efforts of this board fail and the cases go to trial in the Court of Claims, the sum of the awards by that court would exceed the findings that have been made by the board.

Putting these points together, therefore, it is hardly controvertible that if this committee passes the recommendation which is before you, a direct and demonstrable saving of considerable extent will have been vouchsafed the Government.

As to the details of the operations of the board, the complicated wireless instruments which they have studied and analyzed. I do not feel qualified to speak; these matters have already been put before the committee; but I shall be glad now or at any time to answer, so far as I can, any questions which you have to ask.

The Chairman: Does any member of the committee desire to ask any questions at this time?

Mr. Hull: Just one question. What do you estimate is the amount of claims that are not settled by this?

Mr. Curtis: You have touched a very difficult problem there, and I will have to do a little guessing. The situation is this: There are, roughly speaking, two classes of claims, good claims and bad claims. This board has sifted out the wheat from the chaff, so far as it can be done outside of a court, and has determined that certain claims are good and ought to be settled and that certain claims are either bad or at least so doubtful as to make settlement inadvisable. Speaking by and large, these latter claims will probably come up in court, but they are the claims we do not particularly fear. The board has made peace with most of those who had good patents that were infringed, and for the most part has declined to settle only with those who had patents apparently invalid or patents which were not infringed. If those who have been discredited by the board are disgruntled and proceed in the Court of Claims, we have good hopes of confronting them with effective defenses. As to these unsettled claims, I hardly know what to say; they involve claims of some millions of dollars. But, as I said, we feel that in most instances we have defenses against them and look forward with considerable assurance to defeating the majority of those plaintiffs who have not been wise enough to submit to the recommendation of the board. Of course a claimant denied by the board can go to the Court of Claims if he desires. If he does, he will meet the combined strength of the board and counsel for the United States, who will be provided with what we believe are good defenses.

[fol. 2510] Does that answer your question?

Mr. Hull: Yes, sir. Along that line, what as to the future of these claims, does it take into consideration the future use by the Government? Of course, by doing this we admit that the party had a claim against the Government.

Mr. Curtis: Possibly; but I should suggest that you let Commander Loftin answer that question, because it is a phase about which he knows more than I.

Commander Loftin: Do you desire me to say something on that point?

Mr. Hull: Yes, sir.

Commander Loftin: In that connection I am acting in a dual capacity as representing the Bureau of Engineering in radio matters and this board. The Bureau of Engineer-

ing, as you know, purchases the material for radio for the Navy. Now, using the knowledge that this board has gained of the patent situation, we have succeeded in bringing together many of these patents into several of the larger companies and we have succeeded in having those companies practically take care of the Government for the future. For instance, the American Telephone & Telegraph Co. has purchased the Deforest patents—some very important patents to the radio art—and the General Electric Co. has formed the Radio Corporation of America to go into the business of manufacturing radio apparatus and operating radio stations. In doing that they purchased all the Marconi Co.'s interests and combined with those the development of the General Electric Co. and bought out here and there a number of other patents. The International Radio Co., which had a large claim, sold their rights to the Westinghouse Co., so that most of the important patents are held within large organizations and not distributed as they were prior to the commencing of this war. The Radio Corporation and the General Electric Co. and the American Telephone & Telegraph Co. have made an agreement that as far as the Government is concerned any one of those companies can manufacture apparatus for the Government under the patents owned by them, so that gives us at least three competitors from whom we can buy and to expect reasonable prices for the apparatus under a very large group of patents. We also understand that there is in progress an arrangement which will include the Westinghouse Co., so that as far as the future is concerned we feel pretty safe on Government purchases that we will be able to buy from four large companies and can get competition on our proposals for bids.

The Chairman: And at a moderate price?

Commander Loftin: At a modern price; yes, sir; competition from four companies, and in our dealings with them we have always found them willing to supply the Government with apparatus at a very reasonable price.

There are a few other patents that the board has found the Government may be likely to use in the future which are not included in the arrangement among these large companies. In those cases we have secured an arrangement under this settlement proposed to take care of the Government for the life of those patents for a nominal

amount. So, I think it can be safely said that this settlement [fol. 2511] will take care of the future as far as patents which exist to-day are concerned.

Of course, we can not attempt to say as to things which will come after that, but we anticipate, as far as these companies are concerned, that they will give us the benefit of their development: that is, as far as the competition on the part of the four companies is concerned.

The Chairman: I would like to ask you a question. The Dent law, as I remember, provides that a man, in order to get the advantage of that law, had to file his claim before the elapse of a certain amount of time. This provides for a new section passed after the Dent Act was enacted, and there is a doubt in my mind whether that time allowance would apply to this last section, section 6. Do you think it would be advisable to put in the law as we consider it in the House or in the committee a provision that any claim under this section must be submitted to Congress or the proper authorities not later than, say, six months from the date of the passage of the bill? I think the original Dent Act provides for six months.

Commander Loftin: That would include everybody irrespective of time, and I think that should be sufficient, from a practical side. We have practically had before us—and have had for some time—every claim that we anticipate will be brought. The last one of those was probably after that date in the Dent Act.

Mr. Knight: That time ran out in 1919.

The Chairman: I remember that very well. I was one of the conferees on that bill.

Commander Loftin: We have a few claims that were filed after that date, and if that date is going to limit the claims before this board it should be fixed so it will not.

Mr. Knight: Six months after passage of the act would be an abundance of time.

The Chairman: Have you any other suggestion? Could you say three months. These are all war matters and for God's sake let's get rid of the war as soon as possible.

Commander Loftin: I understand, Mr. Chairman, it was four months in the Dent Act, and I think three months in this case would be quite adequate. I do not think there are any more claims and I think three months would be enough.

The Chairman: I thank you very much. What is the name of that case that you referred to?

Commander Loftin: That is the Dent Act.

The Chairman: What is the name of the book?

Mr. Davis: This is volume 1 of Decisions of the War Department Board of Contract Adjustments. That was the board that acted in a semijudicial capacity in enforcing the Dent Act.

The Chairman: This is referred to in that volume as you have suggested?

Mr. Davis: Yes, sir. The Dent Act is printed in this as part of War Department Supply Circular No. 17.

The Chairman: I just want to identify it in the record so that if the committee want to see it we would know just where to find it.

Commander Loftin: Just one other matter. You mentioned this morning some anticipated change in this bill of requiring claimants who do not accept the board's recommendation of proceeding into the Court of Claims within a certain time.

[fol. 2512] The Chairman: That is what I had in mind just now.

Commander Loftin: I thought you meant in the Court of Claims.

The Chairman: If a man does not file his claim in these branches of the Government within the time mentioned in the act I suppose the law provides how soon he may proceed in the Court of Claims.

Commander Loftin: As I understand, there is no limit on that. But he can only claim six years back in his damages.

The Chairman: I presume the moment you begin to interfere with that right in the Court of Claims you immediately enter into trouble, and we have troubles enough on our hands now.

Commander Loftin: The reason we mention that is that we have understood with our claimants right along that whatever happened in the board would be without prejudice, and I was going to suggest if there were an intention of limiting the time they could go into the Court of Claims, it should not be done, as we have never proposed to them that not accepting our recommendation would prejudice the claim.

Mr. Curtis: May I leave you this one thought: That regardless of what may happen in the future, and regardless of the pleasing fact that probably the future is largely taken care of—even if it were not, it would be highly advanta-

geous to the Government in every way to see that this bill passes, since it will undoubtedly insure to the Government a very large saving of money.

The Chairman: We are very much obliged to you gentlemen.

Thereupon, at 3.10 p. m., the committee adjourned until Tuesday, May 24, at 10 o'clock a. m.)

Plaintiff's Exhibit 142.

French Patent for Invention No. 305,060, for "Improvements in Wireless Telegraphy", granted November 3, 1900, to la Société Marconi's Wireless Telegraph Company.

The original exhibit is in the French language. The French patent No. 305,060 is substantially the same as British patent No. 7777 of 1900, granted to Guglielmo Marconi and Marconi's Wireless Telegraph Company, Ltd., (Plaintiff's Exhibit 34 herein) with the following exceptions:

The French patent, page 2, line 3, refers to French patent No. 261,602; the British patent, page 2, line 48, refers to British patent No. 12,039 of 1896.

The French patent, page 5, line 10, refers to French patent No. 283,521; the British patent, page 3, line 28 et, refers to British patents Nos. 12,326 of 1898, 6,982 of 1899, and 25,186 of 1899.

The French patent, page 7, gives figure numbers as 5 to 8, whereas the British patent, page 3, line 48, gives figure numbers 5 to 11.

The matter appearing at the following places in the British patent are omitted from the French patent: page 3, lines 54-55, inclusive; page 5, lines 35-54, inclusive; and page 7, lines 12-14, inclusive, and line 22.

Tunes Nos. 7, 8, and 9 of the Table entitled "Transmitting Station" on page 6 of the British patent are omitted from the corresponding Table in the French patent. Tunes Nos. 7, 8, and 9 of the Table entitled "Receiving Station" on page 7 of the British patent are omitted from the corresponding Table in the French patent.

Figs. 9, 10, and 11 of the British patent are not found in the French patent.

The claims of the two patents differ from each other; those of the British patent appear in Plaintiff's Exhibit 34 and those of the French patent appear in Plaintiff's Exhibit 36.

Claimant's Exhibit No. 150

PLAINTIFF'S EXHIBIT ~~No. 85~~ H 1

~~Dept E Ref~~ June 30th 1899

My dear Parker,

One chief limitation to the utility of the vertical wire of our telegraphy system is that the pedestrian animals in all directions from the transmitting wire so that within the sphere of influence of our vertical wire, all other vertical wire stations are affected by the signals sent from this wire and may not only receive the signals sent from it, but will be interfered with by it in the process of receiving signals from any other vertical wire station from which they may be attempting to receive communication.

This difficulty may be overcome by using transmitting wires giving forth simple harmonic signal waves and receiving stations respond waves or stations only capable of receiving simple harmonic signal waves.

In the existing vertical wire stations, the waves sent out and used to receive messages are complex harmonic waves owing to the fact that the vertical wires are not simple resonators but are capable, upon receiving electrical equilibrium disrupted, of developing oscillation of a

Receipt Exhibit #2

considerable number of different frequencies and also an equal # corresponding more or less perfectly to a corresponding, large number of different frequencies.

Instead of utilizing the vertical wire itself at the transmitting station or the oscillator, I propose to impress upon this vertical wire, oscillations from an oscillator which oscillations should be of a frequency corresponding to the fundamental of the wire. Similarly at the receiving station, I shall draw from the vertical wire, only that component of the complex wave which is of lower frequency.

If now the fundamental of the wire at the receiving station be the same as that of the wire at the transmitting station, then the receiving station may receive signals from the transmitting station, but if it be different from that of the transmitting station, it may not receive those signals.

By such an arrangement it is obvious we shall be enabled to have a large number of vertical wire stations or number

Mr. John Stone Stone,
Phillips Building,
Boston, Mass.

My dear Stone:-

Your letters of July 18th and ~~week~~ June 20 last were received in due course, and have been read with great interest. The "selective" methods of space telegraphy therein described I believe I understand sufficiently to set up and operate them.

Allow me to add that this specialization of the work which Marconi's experiments to date leave in rather primitive condition, is very important, and should be prosecuted without delay by way of further development, and protection by letters-patent.

Yours very cordially,

Jno. L. B. Bates

Defendant

SUPPLEMENTAL BILL

To the Honorable the Judges of the District Court of the United States for the Southern District of New York, in the Second Circuit:

The plaintiff above named, alleges as follows:

First: That the Plaintiff, Marconi Wireless Telegraph Company of America, is a corporation organized and

existing under and by virtue of the laws of the State of New Jersey, and a citizen of said State and a resident of the District of New Jersey within said State.

Second: On information and belief, that the defendant above named, DeForest Radio Telephone & Telegraph Company, at the time or times of the acts of infringement hereinafter complained of was and now is a corporation organized and existing under and by virtue of the laws of the State of Delaware, and a citizen of said States, and at the said time or times had and now has a regular and established place of business in the Borough of Manhattan, City of New York, Southern District of New York, within the State of New York, where it has committed and is now committing some of the acts of infringement hereinafter complained of.

Third: That the above-named plaintiff filed its original amended bill herein against the above-named defendant and another on or about the 28th day of November, 1914, wherein it alleged, among other things, ownership of United States Letters Patent No. 803,684, issued November 7, 1905, to the above-named plaintiff for improvements in Instruments for Converting Alternating Electric Currents into Continuous Currents, upon the invention of John A. Fleming, and charged that the above-named defendant had infringed upon said Letters Patent, and prayed for a discovery, accounting, payment of profits and damages, and for an injunction restraining said defendant from said infringement; that the said defendant duly appeared herein and filed its answer to said original amended bill, alleging, among other things, the invalidity of said Letters Patents, denying the infringement thereof, and setting up other defenses usual in suits for infringement of Letters Patent for inventions; that thereafter issue was joined, a trial on the merits thereof was had in open court, at which a large amount of evidence, [fol. 2530] both expert and fact, was taken by both parties herein on the issues raised; that after further and due proceedings were had, and on or about October 9, 1915, an interlocutory decree was entered herein decreeing, among other things, that claims 1 and 37 of said Letters Patent No. 803,684 were good and valid in law; that said defendant had infringed upon said claims, and granting a perpetual injunction restraining said infringement and an ac-

counting of profits and damages by reason thereof; that subsequently the defendant appealed from said decree and on or about May 8, 1916, the Circuit Court of Appeals for the Second Circuit, after argument on the merits, affirmed said decree; that subsequently and on or about May 28, 1916, an order was entered herein on the mandate of said Circuit Court of Appeals affirming the said interlocutory decree, which orders and decrees remain in full force and effect and unreversed, and all of which will more fully and at large appear by reference to records of this Court and of the said Circuit Court of Appeals, in this suit and to which the plaintiff refers and makes a part of this supplemental bill.

Fourth: That the plaintiff has been, ever since the date of said Letters Patent No. 803,684, and now is, the sole and exclusive owner thereof and of all claims for damages and profits for any infringement thereof.

Fifth: Upon information and belief and by way of supplement: That the aforesaid defendant, since October 1908, and prior to the execution of this supplemental bill, has unlawfully and wrongfully made, sold and caused to be used within the Southern District of New York and elsewhere within the United States, and is now making, selling and causing to be used within said Southern District of New York and elsewhere within the United States, and threatening to continue so to do, devices or wireless telegraph instruments known as "Oscillions" or "Audion Oscillions", containing, embodying or employing the inventions of said claims 1 and 37 of said Letters Patent No. 803,684, or contributing to embodiment and infringement of the inventions of said claims of said Letters Patent and the rights of the plaintiff thereunder.

Sixth: Upon information and belief and by way of supplement, that the said "Oscillions" or "Audion Oscillions" were made and sold and caused to be used as aforesaid, subsequent to the filing herein of the said original amended bill and pending the aforesaid proceedings herein; that the plaintiff, prior to and at the time of filing said original amended bill, was ignorant of the manufacture and sale of said "Oscillions" or "Audion Oscillions" and of the construction and arrangement of said devices and the circuits thereof, and did not acquire any knowledge or sufficient knowledge thereof on which to base any claims in respect

thereto until subsequent to the aforesaid trial under the issues raised by the said amended bill and answer thereto.

Seventh: Upon information and belief and by way of supplement, that said "Oscillions" or "Audion Oscillions" are substantially or essentially the same in construction and mode of operation as the audions, amplifiers and devices adjudged by the aforesaid interlocutory decree to be an infringement of said claims 1 and 37 of said Letters Patent No. 803,684, as the same has been construed by this Court and by the Circuit Court of Appeals for the Second Circuit.

[fol. 2531] *Eighth:* Upon information and belief and by way of supplement, that the defendant has derived and received, and is still deriving and receiving from the said manufacture, sale and use of said "Oscillions" or "Audion Oscillions", great gain and profit, but to what amount the plaintiff is ignorant and cannot set forth, and that by reason of said manufacture, sale and use the defendant has deprived the plaintiff of great gains and profits, but to what amount the plaintiff is ignorant and cannot set forth at present.

Ninth: That by reason of the premises the plaintiff has suffered great loss, damage and injury, and unless said wrongful and unlawful manufacture and sale by the defendant of said "Oscillions" or "Audion Oscillions" is enjoined by the decree of this Court, will continue to suffer great loss and be irreparably injured and damaged.

Wherefore, the plaintiff prays:

1. That it may have the benefit of the evidence and proceedings heretofore had herein, and of any decisions, orders, decrees or injunctions heretofore entered herein or granted against the defendant herein.

2. That the defendant be required to make full, true, direct and perfect answer (but not under oath, an answer under oath being expressly waived) to this supplemental bill of complaint, and that the defendant be required to pay the costs, charges and disbursements of the proceedings under this supplemental bill.

3. That the defendant and its associates, attorneys, clerks, servants, agents, workmen and employees may be provisionally and perpetually enjoined and restrained by the

decree of this Court from directly or indirectly making or causing to be made, using or causing to be used, leasing or causing to be leased, selling or causing to be sold, advertising or offering for sale, use or lease, or causing to be advertised or offered for sale, use or lease, agreeing or contracting to sell or lease, or causing to be agreed or contracted for sale or lease, supplying or causing to be supplied, installing or causing to be installed, or threathening to make, use, lease, sell, supply or install and threatening to offer or contract for sale, lease or supply, or disposing of in any manner, any devices, known as "Oscillions" or "Audion Oscillions", or substantially similar devices embodying or employing, or contributing to the embodiment or employment of said inventions and improvements or discoveries of claims 1 and 37 of said Letters Patent No. 803,684.

4. That the defendant may be decreed to account for and pay over unto the plaintiff all such gains, profits and advantages as have accrued to or have been earned or received by the said defendant, and all such gains, profits and advantages as would have accrued to or been earned by the plaintiff but for the infringement of the said defendant complained of herein, and also all damages the plaintiff has sustained by said infringement of the defendant, and that the Court will assess the same or cause them to be assessed under its direction, and will increase the same, in its discretion, as provided by law.

5. Or that the interlocutory decree heretofore entered herein and the injunctions heretofore issued herein against the defendant be extended to apply to the aforesaid "Oscillions" or "Audion Oscillions" and substantially similar devices.

[fol. 2532] 6. That the plaintiff may have such other and further relief as the premises and the equity of the case may require and as to the Court may seem just.

Marconi Wireless Telegraph Company of America,
by E. J. Nally, *Vice-President.*

Sheffield & Betts, *Plaintiff's Solicitors.* L. F. H. Betts, *of Counsel.*

STATE OF NEW YORK,
County of New York, ss:

On this 14th day of September, 1917, before me came E. J. Nally, to me personally known, who being by me duly

sworn did dispose and say that he is the Vice-President of Marconi Wireless Telegraph Company of America, the plaintiff named in the foregoing supplemental bill of complaint; that he has read the said supplemental bill subscribed by him and knows the contents thereof and that the same is true of his own knowledge except as to matters which are therein stated to be alleged on information and belief, and as to those matters he believes it to be true. That the reason why this verification is not made by the said plaintiff personally is that said plaintiff is a corporation.

E. J. Nally.

Sworn to before me this 14th day of September, 1917.
Walter S. Jones, *Notary Public*, New York County.
(Seal.)

[fol. 2533] IN THE DISTRICT COURT OF THE UNITED STATES FOR THE SOUTHERN DISTRICT OF NEW YORK

In Equity No. 12/31. On Fleming Patent No. 803,684

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA,
Plaintiff,

vs.

DEFOREST RADIO TELEPHONE & TELEGRAPH COMPANY,
Defendant

ANSWER TO SUPPLEMENTAL BILL

The Answer of DeForest Radio Telephone & Telegraph Company, the Defendant herein, to the Supplemental Bill of Complaint of Marconi Wireless Telegraph Company of America.

This defendant, answering, says, as to the following correspondingly numbered paragraphs of the Supplemental Bill:

First: It admits the allegations of Paragraph First.

Second: It admits the allegations of Paragraph Second as to its incorporation and citizenship; but it denies that it has any place of business in the Borough of Manhattan and that it has committed or is committing any of the alleged acts of infringement complained of.

Third: It admits the allegations of Paragraph Third, save that the dates given therein as 1915 and 1916 are erroneous and should be 1916 and 1917 respectively.

Fourth: It has no knowledge as to whether plaintiff was, at the date of the Supplemental Bill, the sole and exclusive owner of the patent sued on or of any or all claims for damages and profits for any infringement thereof.

Fifth: As to the allegations of Paragraphs Fifth and Sixth concerning the alleged infringement, it denies that at any time or at any place it has made, sold or caused to be used, any devices or wireless telegraph instruments known as "Oscillions" or "Audion Oscillions" containing, embodying, or employing the inventions of claims 1 or 37 of Patent 803,684 in suit, or contributing to embodiment and infringement of said claims or either of them or any of the rights of the Plaintiff thereunder; and it avers that the limits of said patent, excluding any and all Oscillion apparatus, are and have been definitely fixed by the Court of Appeals of this Court, by this Court, by the face of the patent itself, and by the prior state of the art; and it further avers that it is doing no business save under its own patents covering the subject matter of the alleged infringement and not previously considered in the prior litigation under the patent in suit.

Sixth: As to the allegations of Paragraph Sixth, concern-
[fol. 2534] ing Plaintiff's knowledge of the alleged infringement, Defendant has no knowledge, and leaves Plaintiff to its necessary proof thereof.

Seventh: As to the allegations of Paragraph Seventh, that the alleged infringements are substantially or essentially the same in construction and mode of operation as the apparatus heretofore adjudged to be infringements of the patent in suit, as the latter has been construed by this Court and by the Court of Appeals of this Circuit, the Defendant denies the same, and in support of its denial refers to the decision of this Court of July 11, 1917, subsequent to the decision of the Court of Appeals, denying an injunction as to the matters now complained of, although extending in other respects the scope of the injunction previously issued and approved by the Court of Appeals.

Eighth: As to the allegations of Paragraph Eighth, it denies that it has derived or received, or is deriving or re-

ceiving from any manufacture, sale or use of "Oscillions" or "Audion Oscillions," any gains or profits; but as to deprivation of the plaintiff of aay gains or profits, it is without knowledge.

Ninth: It is without knowledge as to the allegations of Paragraph Ninth.

Wherefore, Defendant prays that the Supplemental Bill of Complaint be dismissed with costs.

Philip Farnsworth, Solicitor for Defendant, 149 Broadway, New York City, N. Y.

Dated New York, N. Y., October 4, 1917.

[fol. 2535] UNITED STATES DISTRICT COURT, SOUTHERN DISTRICT OF NEW YORK

In Equity 12/31

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA, Plaintiff,

vs.

DEFOREST RADIO TELEPHONE & TELEGRAPH COMPANY, Defendant

New York, N. Y., March 11 and 12, 1919.

Before Hon. Julius M. Mayer, District Judge

March (1919) Term

APPEARANCES:

Messrs. Sheffield & Betts, by L. F. H. Betts, J. Edgar Bull, of Counsel, for the Plaintiff. Samuel E. Darby, Esq., Samuel E. Darby, Jr., Esq., for the Defendant.

PLAINTIFF'S PRIMA FACIE PROOFS

Mr. Bull: Will counsel for the defendant admit that the defendant at the date of the commission of the acts of infringement alleged in the supplemental bill herein, had a

regular and established place of business within the Southern District of New York?

Mr. Darby, Jr.: Yes.

Mr. Bull: Will you admit that this DeForest radio telephone apparatus, bulletin D-16 was issued, published and generally distributed by the defendant subsequent to the filing of the original bill herein and prior to the filing of the supplemental bill herein?

Mr. Darby, Jr.: We admit that the publication was issued and distributed by the DeForest Company prior to those dates, but how generally they were distributed of course I do not know; I am not prepared to state at this time.

Mr. Bull: That is between the date of the filing of the original bill and the date of the filing of the supplemental bill.

Mr. Darby, Jr.: Yes.

Mr. Bull: Will you admit that all the apparatus illustrated and described in said catalogue was manufactured and sold by the defendant within the Southern District of New York [fol. 2536] subsequent to the filing of the original bill herein and prior to the filing of the supplemental bill herein?

Mr. Darby, Jr.: We admit it was offered for sale; I do not know whether it was sold or not.

Mr. Bull: Will you admit that the supplemental bill may be amended *nunc pro tunc* as of its date of filing by inserting paragraph 3, seventh line from the bottom, page 2, "1916" for "1915", and lines 2 and 5, page 3, "1917" for "1916"? Those are clerical errors in the bill.

Mr. Darby, Jr.: These appear to be merely typographical errors and we admit it.

Mr. Bull: Will you admit that the plaintiff is now and has continuously been the sole owner of the Fleming patent in suit since the date of the filing of the original bill herein?

Mr. Darby, Sr.: We have no knowledge as to that; we have no reason to challenge it.

Mr. Bull: Will you admit it for the purposes of this proceeding?

Mr. Darby, Sr.: As far as I know, yes.

Mr. Bull: It is a fact; it will simply save calling a witness.

Mr. Darby, Jr.: If it is a fact we admit it.

Mr. Bull: Your Honor remembers that on the motion an affidavit by Mr. Waterman was filed, a first affidavit, and then a reply affidavit, and a part of those affidavits related to this oscillion matter.

The Court: Yes.

Mr. Bull: If it meets with the approval of the court I will have Mr. Waterman take the stand, have him read what he said in those affidavits as his depositions in this case, simply as a quick way of getting at it.

The Court: I have approved that method on a number of occasions; I think it is satisfactory.

FRANK L. WATERMAN, a witness called on behalf of the plaintiff, being duly sworn, testifies as follows:

Direct examination.

By Mr. Bull:

Q. 1. You have testified as a witness in the trial of the original bill in this case?

A. I did.

Q. 2. Will you explain to the court the references in the catalogue which is marked "Bulletin D-3" of the defendant, the references therein to oscillions, and repeat as your testimony in this case so much of the affidavits filed by you on the motion to extend the decree in this case as you desire.

Mr. Bull: First I will offer in evidence the DeForest Bulletin D-16.

Marked Plaintiff's Exhibit 1.

A. The explanation, I think, will be sufficient if I simply read the portions of the affidavits which I gave on the motion which relate to the oscillion.

Referring now to the so-called "oscillion", I produce as [fol. 2537] Exhibit D, DeForest circular marked Bulletin D-16, entitled "DeForest Radio Telephone Apparatus". This bulletin states as follows:

"DESCRIPTION OF APPARATUS

"As shown in the accompanying cuts the new type of DeForest Radio Telephone is distinctly different from all earlier types. In every particular, from principle to detail, it marks a great advance.

"The arc used in previous types has been completely eliminated. The generator of the high frequency currents is a modification of the now famous DeForest Audion which has been in use for years in the best commercial wireless stations.

"It is entirely fitting, therefore, that a form of this famous device should have been developed into a generator of high frequency currents for telephoning without wires, for its constancy and thorough reliability are its distinguishing features and these are absolutely essential in a practical commercial wireless telephone.

"When this transmitter is adjusted to the desired wave length no further change is required, it being merely necessary to throw the transfer switch from talking to listening or vice versa."

According to my understanding, the sole "modification" of the bulb employed in the oscillion consists in making it larger with accompanying alterations of detail structural features. All the Fleming valve bulbs, including the so-called three element audion exhibited before the Court, have the property of "oscillating" when properly constructed—that is, if they are provided with a sufficiently high vacuum. This means, of course, that they will oscillate provided they are connected in a proper circuit and supplied with a suitable source of local current. This is not an exclusive property of the Fleming Valve, but is a property of other detectors having the same sort of characteristic curves. For Example, Dr. Eccles in his book entitled "Wireless Telegraphy and Telephony", page 220, states as follows:

"Solid conductors may exhibit instability. The possibility of the phenomenon was deduced by the author from the thermodynamic theory of contacts between substances whose resistivity coefficients are negative, and in May, 1910, he showed before the Physical Society of London a galena detector generating oscillations in an oscillatory circuit. The circuits were precisely those of the arc, Fig. 113. In fact the processes in many detectors are reversible; so that if the application of oscillatory voltage to a detector results in the production of a direct current, the passage of a direct current through the detector results in the production of oscillations in a suitable associated circuit. Conversely,

a device for generating oscillations from steady current can be adapted for rectifying A. C.

"Vacuum Tubes as Generators

"Like the contact detector, and for a similar reason, some [fol. 2538] samples of the Fleming valve can be arranged to give oscillatory current in a shunt circuit. On account of the high resistance of the gas path the capacity of the shunt circuit must be small, and the inductance large."

The feature of the circuits usually found essential in causing such oscillations to persist is that the circuit connected to the grid element in the three-element type should be sufficiently closely coupled with the circuit connected to the plate element, so that a disturbance in the one is communicated to the other. When this is the case, then any small disturbance, such as the switching on of the battery in the plate circuit, will cause a disturbance in the tuned circuit connected to the grid element, which will set the latter oscillating. These oscillations are at once detected in the plate circuit and evidenced by an alteration of current therein. This alteration of current again disturbs the grid circuit, which continues, therefore, to oscillate and with an increased energy. This oscillation again creates a current variation in the plate circuit, which is again transferred to the grid circuit, and there is thus built up an oscillating current whose frequency is that of the high frequency circuit connected to the grid element, and which increases in intensity until the energy is lost or abstracted at as great a rate as it can be transferred between the circuits. The device, therefore, becomes a generator and it is this generating action which is used in the heterodyne method of reception, and for creating a high frequency continuous oscillation for measuring purposes of various kinds, and as a transmitter in wireless telephony. As I understand it, therefore, the use of one of these vacuum tubes as a generator is simply one of the well-known uses to which wireless detectors having such a characteristic curve as that possessed by the Fleming valves may be put. Its use in this manner is a mere reversal of its normal functions as stated in the passage of Dr. Eccles' work, just quoted, where he says:

"In fact the processes in many detectors are reversible, so that if the application of oscillatory voltage to a detector

results in the production of a direct current, the passage of a direct current through the detector results in the production of oscillations in a suitable associated circuit. Conversely, a device for generating oscillations from steady current can be adapted for rectifying A. C."

Furthermore, oscillion bulbs are capable of effective use as detectors, particularly as detectors of continuous oscillations. These bulbs when properly connected generate oscillations of radio-frequency, and if used at a receiving station are capable of detecting signals sent out by generators or by transmitting stations using continuous oscillations, and also capable of acting as so-called "amplifiers." Due to the combined effect of the amplifying property of the oscillion and the heterodyne effect due to its own generation of oscillations, its effectiveness for receiving wireless signals of both the damped and undamped or continuous type is apparent.

I will now read from the rebuttal affidavit.

[fol. 2539] With reference to the oscillating audion or oscillion, I observe that it is not denied that, structurally, these bulbs are substantially the same as those already before the Court, save that some of them are larger. It should be pointed out that, as a matter of fact, the bulbs supplied with the DeForest amplifiers, as, for example, the bulbs in Defendant's Exhibit A-4, are oscillating bulbs and in the tests upon Defendant's Exhibit A-4, we so used one or more of them.

The instrument in fact has a switch marked "Ultra-audion", and this so-called "Ultra-audion" is nothing but the ordinary audion provided with means of coupling together the two circuits of the bulb so as to permit of generation of oscillations.

This oscillating action not only supplies a means of giving heterodyne reception, the bulb acting both as the detector and the source of local oscillations, but it greatly increases the sensitiveness of the bulb as a detector for the reception of spark signals. For example, it is a common experience to find that when a given signal from a spark or damped oscillation transmitter cannot be heard at all with a valve (either two or three element) operating as a detector without oscillations, a good signal is obtained when oscillations are set up in the bulb, owing to the increased sensitiveness of the detector which results. These oscillating audions

are, therefore, particularly sensitive as detectors, either for damped or undamped oscillations.

In some recent tests made by Mr. Weagant and myself, for example, the signals being sought were those sent from Carnarvon. The so-called "fancy" circuits were being used. So long as the bulb was not oscillating the signals were inaudible, but upon slightly readjusting (but without change of circuit) so that the bulb oscillated, the sensitiveness was so greatly increased that the signals were not only audible but readable.

Further, it is a fact that, whether the oscillating bulb is used as a detector in the receipt of signals or for some other purpose, its operation in so oscillating is essentially a detecting action. The operations going on within the bulb are assumed to be as follows:

The bulb is provided with two circuits, one an oscillatory, tunable circuit, and the other a battery circuit, and some means is provided for "coupling" the two circuits together electrostatically or electromagnetically (such as a condenser or coil common to the two circuits) so that disturbances in one circuit will be experienced to some extent in the other. When the battery circuit is closed, the filament being heated there is, of course, a flow of current, and the establishment of voltages in the circuit. A charge is, therefore, imparted to the oscillatory circuit, which, of course, gives rise to oscillations therein. These oscillations, acting upon the valve in the ordinary way, produce fluctuations of current in the plate or battery circuit. Since, however, this circuit is coupled to the oscillatory or first-mentioned circuit, energy is again transferred thereto from the battery circuit. If the circuits are properly adjusted this brings about a sustained oscillatory condition, which will continue until something occurs to disturb the equilibrium of adjustment thus established. The operation is quite analogous to the [fol. 2540] well-known whistling phenomena which occurs when a telephone receiver is suddenly brought close to a telephone transmitter. A sustained whistling or squealing sound will frequently be produced.

Dr. DeForest states in his affidavit that he does not know of any way of making a two-element bulb oscillate, and Mr. Stone makes a similar statement. This may easily be accounted for by assuming that they did not have in their hands when they tried to do so bulbs capable of oscillating. It should be borne in mind that, whether such bulbs have

two or three elements does not determine whether they are oscillatory or non-oscillatory. There are two-element bulbs which will oscillate, and three-element bulbs which will not oscillate, no matter what may be the circuit in which they are used. The fact that a two-element valve will oscillate has been known to me for several years, and one circuit in which it will oscillate is the ordinary oscillating circuit used with the oscillating arc, which has been known for many years—as early, in fact, as the year 1900, which is prior to the date of the Fleming patent in suit.

It is unquestionably true that three-element bulbs oscillate more readily than two-element bulbs, so far as my experience enables me to judge, and that the adjustment necessary to produce sustained oscillations is less critical in the three-element bulb.

Mr. John L. Hogan, Jr., in the course of a discussion before the Institute of Radio Engineers, March 3, 1915, said that it was a well known fact that the two-electrode evacuated bulb can be used to produce radio-frequency oscillations. As reported at page 254 of the September 1915 Proceedings of the Institute of Radio Engineers, the statement reads:

"As has been known for some time, radio frequency oscillations can be produced by a simple two-electrode evacuated bulb, but my experience has been that steadier currents may be made by the application of the singing telephone relay principle to the audion repeater."

Q. 3. I will ask you now to demonstrate to the court the oscillating capacity of the two-element bulb.

A. I might explain the apparatus to your Honor while the adjustment is being made. The valve which is being used is the small cylindrical tube having the ordinary filament, and the cold element is a plate simply suspended above it. The circuit which is being used is clearly traceable upon the board. I produce a diagram showing it in which the hieroglyphic which I mark I is the Fleming valve represented in the diagram simply by this filament and plate. The circuit is the P X circuit which was often referred to in the prior case. The regular wireless receiving coil is indicated at the extreme left, the tuning condenser at 3, shunted across it. A stopping condenser is marked C^1.

The local battery circuit is indicated at the right of the bulb and comprises a battery B2. The circuit includes a

telephone in order that the device may be used both to receive and to transmit, and an inductance coil Z which I identify on the board. Shunted across this circuit is a con-
[fol. 2541] denser C2 which I also identify. Identifying the other elements, the coil 2 is at the left, the condenser 3 is just adjacent to it, the transmitting key which will be used to send the signals is shunted across a part of the inductance. That is a common way of transmitting the signals, and it has the effect of changing the period of the oscillations. The adjustment for temperature is by a rheostat here. The stopping condenser is here. This coil is the coil Z, and this is a coil with a single layer wound upon an iron core, the telephones connecting to the circuit as shown in the diagram.

The receiving apparatus is an ordinary receiving set containing the usual coils and condensers, and so forth, of such a set, and is arranged with all the necessary means for causing a three-element bulb, seen at the right, to oscillate and act as a detector. Similarly shunted across the coil of this is a key so that this may be used as a transmitter, and telephones are provided in the circuit so that it may be used as a receiver. Several batteries for the local circuits are seen on the back of the board. I produce a diagram which shows the circuits diagrammatically of the receiving apparatus, located on the right of the table.

Mr. Bull: The diagram is offered in evidence, the diagram of the transmitting.

Marked Plaintiff's Exhibit 2.

I also offer in evidence the diagram of the receiving outfit.

Marked Plaintiff's Exhibit 3.

A. (continued) The Fleming bulb is now being used as a transmitter, and Mr. Weagant is working the key which in practice would determine the sending of signals.

The Court: The court notes a high musical note with a kind of whistling sound.

Mr. Darby, Sr.: May I ask the court to note that in the operation of the apparatus a distinct blue glow appears in the Fleming valve between the filament and the plate?

The Court: Yes, I see that.

By Mr. Bull:

Q. 4. Will you explain what it is that indicates that the two-element valve is acting as a generator of wireless waves?

A. The Fleming valve at the left is being used as a generator of continuous oscillations, the frequency of which was changed by the operation of the key. The instrument at the right is being used as an ordinary heterodyne receiving apparatus, and the operation of the key acts to so change the frequency of oscillations due to the valve, as to bring it within the heterodyne range of the receiving bulb. The heterodyne principle is briefly this: if a set of oscillations are receiving as wireless waves, they cannot be heard in a telephone. If, however, a local source of oscillations is set up and its frequency is so adjusted that there shall be a difference between the two rates, which is an audible rate, then what are called beats will be produced and the audion which is being used as a receiver is oscillating at a frequency [fol. 2542] differing from that at which the Fleming valve is oscillating, which is about, I judged at the time when I heard it, from 600 to 1,000 per second. Therefore, the note which is heard is of that frequency, and when the key transmitter is not operated, no note is heard, which shows that the signal is not being sent at that time at a frequency which is capable of producing an audible tone when combined with that of the receiving valve.

Mr. Bull: I offer to make a demonstration, using the same apparatus inverted so that the three-element valve will act as the generator of continuous oscillations, and the two-element valve will act as the receiver of said oscillations.

The Court: As I view the matter at this time, there is no necessity for the test suggested by Mr. Bull. If, before the trial shall have concluded, either that or some other test seems desirable, we can revert to it.

Mr. Darby, Jr.: Before starting the cross-examination of this witness, if your Honor please, I would like permission—in the first place, may I have the privilege of cross-examining Mr. Weagant who actually operated this machine for your Honor? In connection with the operation of the machine, and when I reach that part of the cross-examination I will have another request, that is, I would like to request permission to operate the device myself if Mr. Waterman and Mr. Weagant have no objection.

Mr. Bull: As to cross-examining Mr. Weagant, I was only going to put one witness on the stand, Mr. Waterman. Mr. Weagant also filed an affidavit simply confirming what Mr. Waterman said. We were before your Honor then on affidavits and it was necessary or desirable to have as the statement of fact more than one witness, so I examined Mr. Weagant. Now, we have demonstrated the thing. It is not a question of what Mr. Waterman says any longer; it is a question of what we have done.

The Court: I will let Mr. Darby ask, if I understand the purport of the request, Mr. Weagant what he did just now in the way of practical demonstration in the courtroom, but as long as the plaintiff has offered only one expert, I do not want to enlarge the number of experts.

Mr. Darby, Jr.: If your Honor please, this is of vital importance to the defendant in this case. Mr. Weagant has given expert testimony in this case ex parte, and it is of vital importance that we be given the opportunity of cross-examining him as to the statements he made under oath in those affidavits. I am perfectly willing to have Mr. Bull offer the pertinent part of Mr. Weagant's testimony so far as the oscillion is concerned in the affidavits he has already made in the case, and allow me to cross examine him on those affidavits. It will not be necessary for him to read it for the purposes of this record.

The Court: You have got your point, I do not know what it is, but we are in this situation. The plaintiff offers an expert. Mr. Weagant has not been offered. At this stage of the [fol. 2543] proceeding I cannot read the affidavit of Mr. Weagant on the motion for the injunction.

Mr. Darby, Jr.: Mr. Waterman has read into the record his affidavits, not only in connection with what he said, but with tests that he and Mr. Weagant conducted. Now, Mr. Weagant was as much a party to that as Mr. Waterman was, and all I ask is the privilege of accepting Mr. Weagant's testimony under affidavit, and allow me the opportunity of cross examining him in so far as Mr. Waterman's and Mr. Weagant's testimony are linked with each other.

Mr. Bull: My friend overlooks the fact that I am captain of the plaintiff's case.

Mr. Darby, Jr.: I do not overlook it. Mr. Waterman has brought in Mr. Weagant in his affidavit, referring to the tests that Mr. Waterman and Mr. Weagant made.

Mr. Bull: Perfectly true; if you want to put Mr. Weagant on the stand as your witness you can do it, but I do not think you can put him on the stand as my witness if I do not choose to call him.

The Court: I will tell you what I think will be the orderly thing. Mr. Weagant can be placed on the stand and submitted for cross examination in regard to the physical facts as to the tests made this morning; that is to say, you may ask him how he used this instrumentality or whatever occurred this morning. Now, in so far as anything beyond that goes, if the plaintiff does not call him, you have the right to call him, but then you call him as your own witness. Of course, you are entitled in the circumstances to latitude on cross examination, as he is not your witness, but beyond the point where the cross examination ceases as to the physical procedure this morning in making the tests for the information of the court,—

Mr. Darby, Jr.: Then I will assume that the affidavit of Mr. Weagant is completely abandoned so far as this case is concerned.

The Court: It is not before me. As my opinion indicated, and as counsel followed out, this is the trial of an equity suit on bill and answer, and what has gone heretofore so far as the affidavits are concerned in respect of the motion, all of that has passed away.

Mr. Darby, Jr.: Is there any objection to Mr. Stone and myself, before we start in the cross examination of this witness, operating the apparatus ourselves?

Mr. Bull: No.

Cross-examination.

By Mr. Darby, Jr.:

X Q. 5. You are financially interested in the Marconi Company, if I am not mistaken?

A. Not in the slightest degree. I do not and never did own a share of stock.

X Q. 6. Or any of the Marconi interests?

A. No.

X Q. 7. Were you not one of the incorporators of the Pan-American Company, I think it is called?

[fol. 2544] A. I believe I am a director in the Pan-American Company at the request of Mr. Nally, but if I own a share of stock, I have never seen it.

X Q. 8. That company, however, is owned and controlled by the Marconi Company?

A. I do not even know that.

X Q. 9. You spoke in your testimony, Mr. Waterman, of the oscillion being a mere reversal of function from a detector; is that correct?

A. Yes.

X Q. 10. By that you mean that it can operate either way; that is what you would consider a fair example of the phenomenon of reversal?

A. I do not know what you imply by the word fair; it is a reversal.

X Q. 11. I will put it a different way. Take an electric motor, you put current on one side and you get mechanical energy on the other side?

A. Yes.

X Q. 12. If you put mechanical energy on that one side you get current on the other side; that is a true example of the reversal function?

A. Under proper conditions that is true, yes.

X Q. 13. You do not have to change anything as far as the motor is concerned, do you?

A. It depends on the circumstances; it depends what the motor is; it depends on all the circumstances of the case. You can arrange it so that you do not have to change anything.

X Q. 14. You can arrange it?

A. Yes.

X Q. 15. That is not so in the case of the oscillion, is it?

A. Yes.

X Q. 16. It is, for transmitting purposes?

A. I did not understand the question was limited to transmitting purposes.

X Q. 17. In other words, you can take the audion as connected in the P N circuit, and either have it receive oscillations, or to generate oscillations?

A. Yes.

X Q. 18. Without any changes whatever?

A. I have done it.

X Q. 19. Without any changes whatever?

A. Yes.

X Q. 20. Used exactly the same batteries, the same strength of currents, you have done that?

A. I do not mean to say without the adjustment of circuit, without any change of circuit.

X Q. 21. You did not have to put in any additional apparatus?

A. No; it is not usual to find a bulb that will do that, but I have done it.

X Q. 22. In fact, it is very unusual?

A. Yes, because ordinarily the valve itself does not furnish coupling enough. When you work under those circumstances the only coupling which you have between the circuits is that furnished by the valve itself. Now, in most valves that is not enough; they do not oscillate readily enough, but I have done it. I would not say that you would find one per cent. of the valves that would do it; you would have to put something in to increase that coupling. The reason for that is this, that in the three-element bulb, one circuit is connected to the filament, and to the grid, and the other to the plate and to the filament. Therefore, the only coupling, the only common part of the circuit, is the space between the grid and the filament.

[fol. 2545] Now, with the two-element valve that is not so because using the same P N circuit, both circuits are connected between the plate and the filament. Therefore you have coupling enough from the bulb itself usually. But with the three-element valve you usually do not have coupling enough, but in certain valves they oscillate perfectly well in the regular P N circuit. Now, ordinarily, you want a coupling, and that coupling may be done either by including the telephones in the common circuit, or by a small coil in the circuit, into the B battery circuit which is put where it is influenced by the grid circuit coil. Any means, in other words, that will carry energy enough over from one circuit to the other is all that is needed.

By the Court:

X Q. 23. Of course, the valves, as has been demonstrated by the cases, vary greatly?

A. Yes, sir; the individual characteristics.

X Q. 24. And the reason for that has never really been ascertained?

A. Not to rationalize it.

By Mr. Darby, Jr.:

X Q. 25. I believe the figures you used were about one per cent, if that high, of the valves could be used in a reversible manner.

The Court: Without coupling, you mean?

A. Yes; without special coupling.

By Mr. Darby, Jr.:

X Q. 26. Without changing the circuit?

A. It is not a change of circuit, Mr. Darby; it is merely changing the relation of the circuits, increasing the tightness of coupling.

X Q. 27. You are adding something which you did not have before.

A. Yes, sir, you are adding the element of coupling.

X Q. 28. That in fact is what you have done in this sketch for transmission, is it not; you have added a coupling there?

A. The three-electrode valve, yes.

X Q. 29. You have added a coupling there?

A. In the receiving arrangement there is a coupling between the two circuits which is indicated by the coils in the two which are related.

X Q. 30. And it is by means of that coupling that you can use that same arrangement for transmission in the test that was offered to be made?

A. Yes. I assume that is the case with that valve; I do not know whether it is or not; I never tried it.

X Q. 31. You have referred, Mr. Waterman, to a statement by Mr. John L. Hogan, supporting your views in connection with the testimony you have given. This statement by Mr. Hogan, as I recall, was after this original suit was filed, was it not; I think the exact date is March 3, 1915.

A. I do not know; if you say it is I will accept it.

Mr. Darby, Jr.: I believe it is the fact; the bill was filed the latter part of 1914.

The Court: Whatever the fact is.

Mr. Betts: We will concede whatever the facts are.

[fol. 2546] X Q. 32. Mr. Hogan was one of the witnesses for the plaintiff in the original hearing; I believe that is a fact too.

Mr. Bull: I note the bill was filed October, 1914.

A. My recollection is he was called, yes; he was called to testify about the hot wire bareter of Professor Fessenden which it had been said was an incandescent lamp and Mr. Hogan was called to say whether or not it was.

X Q. 33. Referring to this circuit in the transmitting circuit, where the inductance is shunted by a condenser, in the P N circuit, for example; I believe both you and Mr. Weagant hotly contested the statement of Mr. Pickard that that was an oscillatory circuit, and in the tests which you made March 6, 1916, you gave some very heated testimony about that point with the result that upon mutual consent some of the testimony was stricken from the record.

Mr. Bull: I object to that.

A. You seem to be designating one diagram and talking about another.

Mr. Bull: I ask for a ruling on that question

Mr. Darby, Jr.: I will come back to that again.

X Q. 34. You noticed this blue glow that occurred in this circuit, Mr. Waterman, when it was acting as an oscillator, as a so-called oscillator.

A. There was a trace of blue glow.

X Q. 35. What is the explanation of that?

A. It is the incipient state of the ionization which is occurring around the edge of the plate. If that blue glow is sufficient, then it would not oscillate. That is true of both two-element and three-element bulbs. If the blue glow really comes between the elements effectively, neither one of them will oscillate.

X Q. 36. Do you know the approximate degree of oscillation of this bulb?

A. No, I do not, except that I know those bulbs were not made for this occasion. Those bulbs are simply samples out of several hundred bulbs which were made many years ago by Mr. Weagant in some work in which I was associated with him, in the investigation of the characteristics of the Fleming valve, and they were all made, in that series, of that shape, and with that shape plate, and they have various spacings, and they are all made with vacuæ of the order of incandescent lamps, or better. That bulb from its behavior

I would say had a vacuum of the order of the better incandescent lamps of Fleming's time.

X Q. 37. To get back to the blue glow, it extended from the filament to the plate?

A. No; I did not say that.

Mr. Darby, Jr.: Would you mind showing that, Mr. Weagant, for the benefit of this witness. I would like to show that blue glow does extend between the plate and the filament.

(Mr. Weagant makes demonstration.)

X Q. 38. It practically fills the space between the plate and the filament?

A. I would be very glad to admit it if I could see it, but I cannot see it. That is the usual edge blue which indicates [fol. 2547] that if you could push it harder it would blow over and go out of action, and that is where most of the bulbs, both the two-element and the three-element, have to be worked, where the spacing is as great as it is in this bulb. You recognize that is a very wide spacing, but in the ordinary commercial bulbs the spacing is only a trivial fraction of that spacing.

Now, it is my fault that we have not special bulbs here. I told Mr. Weagant not to make special bulbs. I wanted to have him just take bulbs which he had made with no thought of oscillations in mind, and I went down there and helped him select it, and we went through several hundred bulbs, and I guess we found fifty that would oscillate. Some of them oscillated better than others, and there are a few of them here in court. But I told him I did not want him to make valves for this very case, and in these long space bulbs you will always find that the local battery required is high on account of the spacing, and you will always find they work best when they are approaching the blue glow such as this, always indicated by the edge glow.

X Q. 39. Have you ever made one of these bulbs oscillate when you did not have the blue glow?

A. I do not know as I looked for it as critically as you did, but I have known them to oscillate when I did not see a blue glow.

X Q. 40. Is not in fact the blue glow striking an arc between the two electrodes: when this bulb is generating os-

cillations, as you say it does, have you not established an arc between the two electrodes?

A. Well, Mr. Darby, I began working with arcs in 1888, and I have not yet heard anyone define one. If you can define an arc to me I can answer your question.

X Q. 41. Will you please answer the question?

A. I do not call that an arc, nor do I call that anything which in any way resembles an arc.

X Q. 42. You say that it does not in any way resemble an arc?

A. Yes; that is my understanding of it.

X Q. 43. What would you consider to be a fair description of an arc, as a scientific man?

A. An arc is the most difficult thing that in all my experience I have run across to define. Now, I am not willing to say that I can define an arc, but I can define certain things which unquestionably are arcs, without saying that I can limit the definition. When you connect a circuit between carbon pencils in the air and separate the pencils you draw that which everyone agrees is an arc if you have a sustained current flow. Now, that arc is a passage of current through the space separating two electrodes, using as the conveyor for current the vaporized material of the terminals. That is an arc and that definition will I think pass muster anywhere as being an arc. Now, you may have an arc under another condition.

X Q. 44. I do not believe it is necessary to go any further into that; that definition that you have given I am perfectly willing to accept. An arc, according to your definition, is where due to vapor a conducting path is established between two separate terminals.

A. Due to the vapor of the electrode.

X Q. 45. Accepting that definition, have you not established an arc between the filament and the electrodes in this [fol. 2548] valve?

A. You certainly have not.

X Q. 47. You are quite positive of that?

A. I am absolutely certain about it.

X Q. 47. As a matter of fact, Mr. Waterman, are you generating the current that comes from the bulb itself between the two terminals; is that oscillating current or alternating current, or is it pulsating current?

A. I never saw its picture, but I take it to be an oscillating current, but I do not see that it makes any difference.

X Q. 48. In other words, there is very little difference between pulsating and oscillating; there is a distinction, of course.

A. No; I do not know what the distinction is unless it is one of wave form, and I do not see that wave form interests us.

X Q. 49. Then it is immaterial whether it is pulsating or oscillating so far as its operation as a generator is concerned?

A. I did not say that. I do not know what restriction you put on the words. As I interpret them I should say it was immaterial if you merely mean to raise the question whether or not there is a true sine wave form there.

X Q. 50. First you say there is practically no distinction between them and then you will not admit that there is no distinction?

A. I did not say there was no distinction; I said I did not know what the distinction was.

X Q. 51. Do you know the difference between them?

A. I do not know how you use the term.

X Q. 52. I am trying to use the term in perfectly plain English; what is the difference between a pulsating current and an oscillating current?

A. I would say that all of these bulbs necessarily give what I now understand you mean by pulsating current. None of them oscillate because none of them go through zero; in other words, we have always a battery; we have always therefore a direct current through the space. Now, when we say it oscillates we do not mean there is an alternating current.

Mr. Darby, Jr.: If your Honor please, I asked the question as to what is the difference between oscillating currents and pulsating currents if he finds any difference.

The Court: His answer is along proper lines; I will let him continue.

A. (continued) That direct current during the oscillating process never fails to zero, so that what really is happening is that the direct current is pulsating; it is going up and down. If that is what you mean by pulsating, that the current never goes through zero, I agree most decidedly with that; that I think is universally accepted, that in none of these bulbs does the current in the plate circuit ever go through zero; the current in the high frequency circuit, however, is a real oscillating current.

X Q. 53. I understand you then that the current which is generated, to use that expression, by that valve structure, is oscillating current.

A. Of which circuit are you speaking?

X Q. 54. Of the circuit connected between the two terminals of the Fleming valve when it is used as a generator; is that pulsating according to your definition, and I think [fol. 2549] we are agreed on the definition, or is it oscillating current?

A. The current which is passing through the plate circuit is an alternating current, superposed upon the direct current. Therefore, it never goes through zero and is what I now understand you to mean by pulsating. The current in the circuit at the left in diagram Plaintiff's Exhibit 2, and which was received as a signal at the other end of the table, representing the receiving station, that is an oscillating current in that it is not superposed on a battery current.

By the Court:

X Q. 55. When you referred to the other end of the table you were referring to the device here in court on which the experiments were made?

A. Yes; I was referring to that part of it which was used as a receiving station.

By Mr. Darby, Jr.:

X Q. 56. You are in fact referring to the three-electrode arrangement for reception?

A. I am referring to the current which was received by the three-electrode arrangement; that was an oscillating current.

X Q. 57. And the current at the transmitting station between the two electrodes of the Fleming valve is a pulsating current?

A. In the same sense that it always is in those bulbs, whether two or three element, yes.

X Q. 58. In the three electrode audion is it a pulsating current or an alternating current?

A. In the battery circuit it is a pulsating current; that is, one which never goes through zero.

X Q. 59. You mean in the circuit connecting the plate electrode and the filament electrode?

A. Yes.

X Q. 60. That is what you call the battery circuit?

A. Yes.

X Q. 61. Of course, it is perfectly apparent that while this Fleming valve structure is operating as a generator, it is not operating as a detector; you agree to that?

A. That is so much a matter of definition that I hardly know what you mean. I could hardly agree to that without taking back what I said in my prima facie case. To me the action is essentially a detecting action.

X Q. 62. When it is generating oscillations?

A. Yes; in other words, it is the detecting action that maintains the oscillation.

X Q. 63. You could substitute for this bulb a high frequency dynamo, could you not, or an alternating current dynamo; would that still be a detector?

A. If I had it I could, and it would of course not be a detector. If I may add to that, I do not want to be misunderstood here, your present question is different from your preceding one. The preceding one involved the question whether it was acting as a detector; as after the manner or in a similar way to a detector. Your second question asked me whether it would be a detector. Now, it would not be a detector, and the bulb is not a detector, but the bulb is acting after the manner of a detector in the act of generating.

X Q. 64. That is what I was very anxious to get at; if you inserted an alternating current dynamo, it would work just as well as with this valve, would it not; that is, it would [fol. 2550] work successfully?

A. I do not know of any alternating current that would give that frequency, but if you had one it would.

X Q. 65. It would perform the same function, of course?

A. As a transmitter, yes.

X Q. 66. And a dynamo, of course, could not function as a detector?

A. But that operates for an entirely different reason.

X Q. 67. That is true; when this bulb is operating as a generator it is not operating at the same time as a rectifier, is it?

A. In the sense that it can only conduct one way, yes.

X Q. 68. In the sense that it is detecting and rectifying alternating currents, it is not acting in that manner, is it, when it is generating electrical oscillations—I do not intend to put indefinite questions to you; that is a very simple question. I think you have said already that when it is generat-

ing oscillations it is not detecting; you have said, of course, it depends upon the same function.

A. I said it is not acting as a detector.

X Q. 69. It is not acting as a combined detector and rectifier?

A. I do not know.

X Q. 70. You said it is not acting as a detector; do you not know whether it is acting as a combined detector or rectifier?

A. I do not follow your use of terms. Obviously it is not acting as a detector because it is not being used as a detector. Now, according to my understanding, similar operations are going on within it, identically similar operations are going on within it, to those that would be going on within it if it was being used as a detector. Possibly that will answer your question.

X Q. 71. Suppose I put it to you this way. Assume for the moment that my definition of the Fleming invention is a combined detector and rectifier, is this bulb when it is generating electrical oscillations acting as a combined detector and rectifier?

A. I do not know what you mean by those words. Similar sorts of actions are going on. You are utilizing the characteristic curve in both cases. I cannot pretend to know precisely what you mean by your use of the word rectifier.

X Q. 72. You have great difficulty in understanding that question; might I put it this way?

The Court: You see, there is probably a surviving controversy as to what rectifying means; that is his point, among others.

Mr. Darby, Jr.: If your Honor please, I think the question is perfectly clear. I am asking this witness to admit what is an obvious fact, and the difficulty is in having him admit it. The cause for the difficulty I cannot understand.

X Q. 73. When that bulb is acting as a generator of electrical oscillations, is it functioning as a detector and rectifier?

A. Certainly it is not functioning as a detector. When I say that I do not take back what I said on my direct examination.

X Q. 74. Of course, it is unnecessary to ask whether you are familiar with the Fleming patent.

A. I am familiar with it.

X Q. 75. May I ask if there is any part of the Fleming patent which states, or which to you as an expert in the art [fol. 2551] would instruct you that that device could be used for the generation of electrical oscillations, and if so point out any such passage.

A. Not specifically, of course.

X Q. 76. My question was if there is anything in the patent.

A. My answer is there is nothing that has any specific reference to it.

X Q. 77. Is there anything in that patent which to you as an expert in the art would instruct you or tell you that that device could be used as a generator of electrical oscillations and if so, point out the particular passage.

A. I do not think there is. I do not think that at the date of the Fleming patent I would have derived from it the understanding that that would oscillate, but after learning that detectors which are able to amplify oscillate, knowing the telephone oscillation phenomenon, knowing that this device does amplify as a matter of fact, I would have no difficulty in understanding that it must be capable of oscillating and generating.

X Q. 78. Did you not know that any two-electrode device would generate electrical oscillations as of 1905, and by device I mean a vacuum tube.

A. No; I did not know that.

X Q. 79. I will read a passage of your affidavit made in this case—I do not recall whether this particular passage is in the record.

"There are two element bulbs which will oscillate and three-element bulbs which will not oscillate, no matter what may be the circuit in which they are used. The fact that a two-element valve will oscillate has been known to me for several years, and one circuit in which it will oscillate is the ordinary oscillating circuit used with the oscillating arc, which has been known for many years—as early, in fact, as the year 1900."

You are familiar with that?

A. I was.

X Q. 80. What is the distinction between what you referred to there and your answer to my last question?

A. I understood your last question to ask me whether I would have known in 1905 that any two-electrode vacuum

bulb would oscillate. I do not see any relation between the two myself.

The Court: You see in the testimony just referred to he said he had this knowledge for several years; in the other question he was asked as to 1905.

By the Court:

X Q. 81. This knowledge, I assume from your answer, was only acquired later than 1905?

A. That is quite right; there was the Poulsen arc.

By Mr. Darby:

X Q. 82. You did not refer to a vacuum tube there?

A. No.

X Q. 83. Have you ever heard of the Geissler tube?

A. I have.

X Q. 84. Had you heard of it in 1905?

A. Yes.

[fol. 2552] X Q. 85. Had you ever heard that Geissler tubes would generate oscillations?

A. No, sir, never.

X Q. 86. That is a two-electrode valve, is it not?

A. It has not got any electrodes.

X Q. 87. What is known as the Geissler tube has no electrode?

A. The Geissler tube does not need to have any electrodes.

X Q. 88. Have you ever seen prior to 1905 a Geissler tube?

A. Yes.

X Q. 89. With two electrodes in it?

A. I think so.

X Q. 90. But you did not know in 1905 that the Geissler tube would generate oscillations?

A. I do not know it now.

XQ. 91. You do not know it now?

A. No.

XQ. 92. You are not in a position to deny it, though?

A. No.

XQ. 93. The Geissler tube, the two-electrode tube that I referred to consists of a tube with two electrodes separated from each other, separated in substantially the same manner as the plate and filament electrodes are separated from each other, so far as the tube structure itself is concerned: is that correct?

A. I do not think your question is complete; make your question clear. If you will make it clear you are talking about a bulb there.

XQ. 94. I am referring to the Fleming bulb.

A. I never saw a Geissler tube which would at all compare with the description of your question. The Geissler tubes which I have seen are long, slender tubes having a wire sealed in at each end, and separated six, eight, ten inches, as the case may be, and they do not in any way resemble the construction of this valve, either as to the separation of the elements or as to the character of the elements.

XQ. 95. You mean they are separated a little greater distance than the filament and plate of the Fleming valve?

A. If ten, twenty, or thirty times is a little greater, yes.

XQ. 96. That would make it a great deal difficult to create electrical oscillations, would it not?

A. I do not know.

XQ. 97. If I show you a patent of 1892, a British patent to Hutin & Leblanc, No. 23,892, of 1892, stating an alternating current of high frequency produced at a central station by an interrupter of continuous current, or by a passage of the current through vacuum tubes is sent, and so forth, would you agree that it was known in 1905 that a two-electrode tube or a vacuum tube was known for the generation of the electrical oscillations?

A. I do not know.

XQ. 98. Do you agree with that statement?

A. I have not seen it.

Mr. Bull: I object to that, your Honor.

The Court: I cannot see how this is material to the controversy.

Mr. Darby, Jr.: Your Honor, it is material, in this respect. One of our positions, which is not inconsistent with other positions which we have to take in this case, is the minute the Marconi Company, or Mr. Waterman, makes this device act as a generator, they are compelled to ignore the Fleming invention, and they are coming to the point where [fol. 2553] they are doing what was done years before, known in 1892, using two electrodes separated from each other in a vessel, in a tube, and having it set up oscillations. In other words,—I can see that your Honor does not quite get the point that I have to make. I did not want to make it

at this time—the only distinction between Fleming and the prior art devices is that it uses a hot electrode, and I am prepared to show your Honor that the hot electrode has absolutely nothing to do with its operating as a generator, and as a fact it is detrimental to its operation as a generator. Secondly, I believe it is very pertinent on the question as to whether or not the oscillion is an infringement of the Fleming valve merely because it uses a hot electrode which is absolutely essential to its operation, and the Fleming valve uses a hot electrode which is absolutely a detriment to its operation.

Mr. Bull: Now that my learned friend has stated what his purpose is, it is very evident that this is absolutely not germane to anything which we are considering here. The relating of the prior art to the Fleming invention has been gone into fully and it has been finally determined, as to the prior art and its relation to the Fleming device. I understand now he is going to attack the Fleming patent.

Mr. Darby, Jr.: Absolutely, so far as the oscillion is concerned.

Mr. Bull. We are to determine the question as to whether this same Fleming device used as a generator of wireless waves is an infringement of the Fleming patent and what we are here today to do is, as I understand it, and the only thing we are expected to do, or that it is desired we should do, was to show your Honor, convince your Honor that this thing would oscillate. When we were before you before Mr. Waterman and Mr. Weagant said it would oscillate. Now, Mr. Stone and Dr. DeForest said it would not oscillate. These proceedings were started for the purpose of ascertaining which were right.

The Court: I think there are only two issues in the case in view of the previous litigation. One is whether in point of fact the Fleming valve does the generation of the oscillations which the plaintiff claims. That is the question of fact in the case. Secondly, there may be a question of law involved as to whether, taking the Fleming patent as it was written, the Fleming patent can be availed of to cover an instrumentality such as this, whose operation was not in 1905 perhaps understood or fully understood. That is the secondary question which is a question of law. That is all there is to the case. I am not going to let any opening up of the prior art at all because that is nothing but in effect—

I do not mean to say you have not the right to press the point—but it is nothi ·· in effect other than reopening the Fleming case, Marconi v. DeForest, which has gone through this court and the Circuit Court of Appeals. I would have been in a position to decide the motion on the preliminary [fol. 2554] injunction if it were not for the contest of the fact in the affidavits which made it necessary for me to determine this fact, as I explained in my opinion, in orderly fashion, where demonstration could be had, and a witness or witnesses could be examined and cross examined to see whether in point of fact this thing oscillated or it did not. We did have the Hutin & Leblanc patent in some litigation, but I am going to make the issue very narrow and if I am in error you go up on a thin record, one side or the other, and if I am not in error, that is the end of it.

Mr. Darby, Sr.: But it is not the purpose to go into the prior art; the purpose is in the present case, it is only necessary, as we conceive it, to consider the prior art with reference to the bearing on the second point that your Honor makes, and that is the question of law; whether or not the Fleming patent can be construed as a grant in the light of what it contains within itself, with sufficient breadth and scope to include something which is not referred to in that patent, not described, a characteristic which is not mentioned in the remotest way.

The Court: That seems to turn solely on the question of law,—how much of a dragnet is the patent. That involves a consideration of perhaps two or three principles of the patent law, one of which is that, of course, normally a man is entitled to all of the approximate results, even though he did not foresee them. The other is how liberal shall you be with the patent which involves an understanding of what that patent represented in the way of inventive thought and advance in the art. Those are the two cardinal principles that govern here and those are the only questions of law. Now, if Hutin and Leblanc used some words in 1892 which now in 1919 somebody or other can construe in the light of after events as meaning something that nobody ever thought about, we are going to get into a wilderness.

Mr. Darby, Sr.: That is not the purpose.

The Court: I sustain the objection.

Mr. Darby, Jr.: The whole point I had in mind was this, on the second point, which we will accept and confine ourselves strictly to in this case, and I will ask your Honor is

it not pertinent to show that the use of a generator which they are seeking to carry in this dragnet, is it not pertinent to show that that is old over their particular device; is not that pertinent; it is old at the time of their patent.

Mr. Bull: We have already determined this case; that that particular device is new.

Mr. Darby, Jr.: Not as an oscillator.

The Court: I will adhere to my ruling. I am perfectly clear as to what I have in my mind; I may be wrong, but I am clear about it.

Mr. Darby, Jr.: Exception.

X Q. 99. You have noted that in 1892 the use of a two-[fol. 2555] electrode vacuum tube for the production of the generation of electrical oscillations was old?

Mr. Bull: I object to that. Objection sustained; exception.

X Q. 100. I believe you stated, Mr. Waterman, that the use of the valve as an oscillator or generator of oscillations depends upon its function as an amplifier; is that correct?

A. Yes; that is, I do not understand that a bulb which will not amplify will oscillate.

X Q. 101. You do not understand that a valve which will not amplify will oscillate?

A. Right.

X Q. 102. And I believe it is your contention that the Fleming invention further includes both amplification and oscillation?

A. I make no contention as to the invention at all; I know that Fleming bulbs will amplify and will oscillate.

X Q. 103. I believe you have given testimony that the Fleming invention is present.

Mr. Bull: I do not think he is allowed to do that.

The Court: That is not allowed.

By the Court:

Q. 104. So far as you are familiar with the art can you tell me when this oscillation feature was realized?

A. I think I first knew it in 1913, your Honor.

Q. 105. Was that the result of experiments, or what; I mean, the ascertainment of that knowledge?

A. That was the result so far as my personal knowledge is concerned, of the work of Mr. Weagant and Mr. Arm-

strong. I was personally familiar with Mr. Weagant's work, and Mr. Armstrong's work I learned of through statements made to me by Mr. Weagant.

Q. 106. Then so far as that oscillation feature is concerned what it comes down to is this, does it not, and see if I have it right; that from the time of the Fleming patent in 1905 up to 1913, the time that this knowledge came to you, there had been a constant development in the general direction of greater knowledge of the phenomenon affecting radio?

A. Yes; that is right.

Q. 107. That is to say, that while many of the reasons for certain actions were still either unknown or debatable among scientists, the fact that certain things happened had become known?

A. Yes.

Q. 108. And this oscillation feature, or the knowledge of the oscillation, came in the course of the development of facts, to the attention of yourself and presumably other men who were concerned with a study of the art?

A. That is correct. My first knowledge of the oscillation of these tubes was as to the three-element tube. Naturally, that raised the question whether the two-element tubes would also oscillate, and on trying it we found that they would.

Q. 109. So that, putting it in another way, when this fact of oscillation became known then you endeavored to find out whether the Fleming valve would oscillate?

A. That is exactly what happened.

[fol. 2556] By Mr. Darby, Jr.:

X Q. 110. You say in 1913 you became familiar with the fact that the three-electrode valve would oscillate. You are quite sure of your date as to that?

A. No; I have not looked it up. I do not know that I could fix it. I only fix it by my recollection as probably 1913.

By the Court:

Q. 111. I suppose you are not able to definitely state 1913; it may be 1914?

A. It may be 1914, but from other events my impression is it is in 1913.

Q. 112. It is not important except as indicating that a period of years had passed from the time of the Fleming patent until this realization came about.

A. Yes.

By Mr. Darby, Jr.:

X Q. 113. Did you assist Mr. Weagant in these tests in finding that the three electrode devices would oscillate?

A. No. Mr. Weagant was engaged in the work—it is his custom to work both night and day—and he worked daytimes, and I living only a few miles away from him very frequently ran down by automobile and worked with him at night and he showed me the phenomenon, as I remember it, after having discovered it himself. I remember he showed it to me as to both the three and the two-element bulbs, but my recollection is that he showed it to me as to the three-element bulb first, and later we received signals, transatlantic signals, with the two-element bulb, acting as an oscillating heterodyne machine.

By the Court:

Q. 114. Will you state on the record in a sort of summary way what difference if any there is between the physical installation in the court room now and the physical installation under the Fleming patent?

A. In the first place, the circuit which is used in the physical installation as affecting the Fleming valve in this court is the P N circuit, and not the other circuit, although I have more usually used and seen used the other circuit, that is the literal circuit of the Fleming patent.

The difference in precise detail between a P N circuit as here used and the P N circuit as was before your Honor in the exhibit DeForest box which was in evidence, is the addition of the coil Z which was not involved in that. That coil Z has the effect of adding to the apparent inductance of the telephone, and that is what it is there for, and the reason that it is desirable to add to the inductance of the telephone is that it gives a greater energy storage, and in order to supply energy rapidly as demanded by the bulbs, some storage is desirable, although it is not absolutely essential. Then, of course, the transmitting key is an additional feature.

Mr. Darby, Jr.: I was trying as far as possible to keep the testimony concerning this particular apparatus separate from the rest. I intended to cross examine on that particu- [fol. 2557] lar point, and there are several questions I want to ask Mr. Waterman in connection with this circuit which I will defer for just a minute.

By Mr. Darby, Jr.:

XQ. 115. You said a few minutes ago that you became familiar with the Fleming valve as an oscillator quite recently: that is, fairly recently, subsequent to 1913 or 1914.

A. About that time.

XQ. 116. After Mr. Weagant had demonstrated to you that the three-electrode valve would oscillate?

A. I think it occurred in that order.

XQ. 117. When did you first have knowledge of the Fleming valve as a detector for wireless?

A. I could not say.

XQ. 118. You do not recall, you mean?

A. I think probably not very far from the time when Fleming first announced it.

XQ. 119. You were familiar with the Fleming patent about the time it was issued, or shortly afterwards?

A. No; I had no interest of an especial nature in wireless telegraphy until about 1911, as I remember, or 1910. My interests prior to that time was merely that of keeping ordinarily well informed in scientific matters.

XQ. 120. When did you first know of the Fleming patent as a patent?

A. I should say it was not so very long before the institution of this suit of which this is a continuation.

XQ. 121. You did not know that the Fleming patent was in existence until just a short time before this suit?

A. I should not say more than a year or so before that; possibly two years.

XQ. 122. Of course, you were not familiar with the use of the Fleming valve as a detector in 1905 then, if you did not know of the patent?

A. Not from any personal knowledge of it; I knew of its existence and use by others as a detector, but I had no experience with it.

XQ. 123. In 1905?

A. I would not say that.

XQ. 124. Around that time?

A. I first read about it in a paper I think published by Fleming in the ordinary course of scientific reading.

XQ. 125. You did not use one of them yourself as a detector until subsequent to 1911?

A. That is correct.

XQ. 126. I would like to read a statement, bearing in mind your answer to a question a little while ago, to the effect that an oscillator must necessarily be an amplifier. I am reading from a statement made by counsel for Dr. Fleming himself, the patentee, in the British case in which the corresponding British patent was involved.

Mr. Bull: I object to that as immaterial.

Mr. Darby Jr.: Dr. Fleming himself was a party to this proceeding and appeared personally in court, and the statement that I will read from is the statement made by his leading counsel.

The Court: How is that material? Suppose that leading counsel got up and said that Fleming did not invent anything at all. Such a statement cannot bind the people [fol. 2358] who own the patent. They take the patent for what it is worth, and the development of patent cases has indicated that time and again there is a misapprehension; either sometimes too much is attributed to the patent, sometimes too little. Statements of that kind are not in any sense germane.

Mr. Darby, Jr.: It goes further than that; it goes into the invention.

The Court: It cannot; Mr. Fessenden in Kintner *v.* The Atlantic, endeavored to disown his own child but without success; I mean, with success but not on that ground.

Mr. Darby, Jr.: The Marconi Company of England which is a stockholder of the Marconi Company of America were vitally interested. But the point is this; they have a suit in the United States on one ground and in England on another ground. To substantiate both suits they have got to take absolutely opposite positions.

The Court: That does not make any difference, either.

Mr. Darby, Jr.: They produce the man who originally drew the Fleming patent.

The Court: I will sustain the objection on the ground that it is utterly immaterial.

Mr. Darby, Jr.: Exception.

Mr. Darby, Sr.: In order to make the record clear, the offer is to read extracts from the record in the high court of justice, Chancery Division, London, England, trial before Justice Sargent in the matter of Fleming Patent No. 24,850 of 1904, and in the matter of the Patents and Designs Act of 1907, petition for prolongation; excerpts from the transcript of record of Mr. J. Hunter Gray, K. C. as counsel for the petitioners, the Marconi Company, and Professor Fleming.

The Court: That is the defendant Marconi Company?

Mr. Darby, Sr.: Yes, and Professor Fleming, the patentee of the patent in suit, and also extracts from the testimony given by witnesses called in behalf of the petitioners in that case, and also from the judgment of the court entered in the case.

The Court: What date is that?

Mr. Darby, Jr.: It started the 4th day of December, 1918, and lasted nine days.

The Court: As I understand it, there are some statements of counsel and witnesses exhibiting their views as to the scope of the patent.

Mr. Darby, Jr.: And the invention itself.

The Court: And the invention itself, in a litigation between entirely different parties from those that are here present.

Mr. Darby, Sr.: But involving the same subject matter.

The Court: Yes; involving the same subject matter. I will sustain the objection as far as the testimony is concerned. Of course, it is always permissible by way of argument in briefs to present the judgment of any court on the same subject matter.

[fol. 2559] By Mr. Darby, Jr.:

X Q. 127. Mr. Waterman, will you please explain why you have used an oscillating audion in this demonstration?

A. I do not know of any other way of receiving the undamped oscillations that I could conveniently bring to court.

(After recess.)

X Q. 128. The blue glow effect which was noticed in this bulb is due to the amount of voltage which was used to cause the device to generate electrical oscillations; that is correct, is it not?

A. Yes; the voltage in the plate circuit.

X Q. 129. Would the two-electrode Fleming valve device using a battery current of sufficient potential to cause the blue glow to appear, operate effectively as a detector for radio purposes?

A. Yes; in the condition in which the bulb was seen this morning, it will neither oscillate nor detect if the blue glow is too pronounced. The blue glow is a pure incident to certain valves; that particular one happens to work at that point on the characteristic curve; that is all.

X Q. 130. If you were to use this valve for detecting purposes you would not use the same amount of voltage in the circuit as you would use when it is connected for generation purposes, would you?

A. I think so, yes.

X Q. 131. You would use the same amount of voltage?

A. Yes.

X Q. 132. What is the amount *for* voltage that is employed in the oscillating circuit of the Fleming two-electrode device as demonstrated by this apparatus?

A. I did not notice that; I can ascertain it.

Mr. Bull: You can ascertain by having Mr. Weagant tell it.

X Q. 133. In using this device, and I refer to the Fleming two-electrode device for detection purposes, what is the amount of voltage that you employed in the circuit?

A. It depends upon the individual valve and upon what particular part of the characteristic curve you are working on.

X Q. 134. What is the maximum voltage which you have ever used for that purpose?

A. In valves of that construction, I should say around 100 volts; maybe 200; I cannot say to a certainty.

X Q. 135. I am asking you what is the maximum voltage which you have ever employed in connection with a two-electrode valve for detection purposes?

A. That is what I was answering to. In my own station, I customarily have only about 100 volts and I have used about all of that, I am sure, but when I have been working with Mr. Weagant he had higher voltages, and I do not know whether he used them or not on these particular tubes. I should think these tubes the voltage ran between 25 and 100.

X Q. 136. What is the normal voltage that is used in the actual commercial use of this detector?

A. Are you speaking of valves of this particular type?

[fol. 2560] X Q. 137. Any two-electrode type.

A. Well, they have often been used with no voltage at all.

X Q. 138. For detection purposes?

A. I think in the customary commercial use that I have been familiar with it is between zero and twelve volts. These bulbs, however, have a greater separation between filament and plate, and therefore take a higher voltage.

By Mr. Bull:

Q. 139. You mean the bulb?

A. I mean the bulb of which the individual here in court is a sample.

By Mr. Darby, Jr.:

X Q. 140. You have witnessed, of course, the two-electrode bulb used for detection purposes commercially, have you?

A. Yes.

X Q. 141. In that particular instance, do you recall what the voltage was?

A. No; I do not.

X Q. 142. You could not limit it; you could not come within limits of which you feel certain it was used?

A. The limit of the total storage battery I believe was 12 volts.

X Q. 143. You have stated in your testimony that the Fleming two-electrode device if properly constructed—I think those are the exact words you used—will oscillate: that is correct?

A. Yes.

X Q. 144. Do you find any information in the Fleming Patent as to instructions as to how to properly construct the Fleming valve device to cause it to generate oscillations?

A. Yes.

X Q. 145. Will you refer to the particular passage please that tells you what the proper construction is?

A. Well, at page 1, line 71.

X Q. 146. Will you please read it?

A. It says, "I generally heat the carbon filament to a high state of incandescence by a continuous electric current." That is one of the essentials.

X Q. 147. Before we go to the next essential, will you please tell me what is contained in that statement which tells you how to properly construct the Fleming valve structure to cause it to generate electrical oscillations.

A. It is only a matter of so proportioning the filament that with the battery to be used the filament will heat to a bright incandescence.

X Q. 148. Then, as I understand you, before we get to the next point, that the only proper construction of the bulb is the amount of current that you have got to supply to the filament?

A. I said that is one feature.

X Q. 149. Am I correct that what you had in mind was not the proper construction of the bulb but the amount of current that is used for the filament; is that correct?

A. That is a matter of construction of the bulb in the ordinary sense. If you are constructing to meet a certain set of conditions you must so construct your filament that it can be brought to a very high state of incandescence. That is one of the necessary conditions. I was going to refer to another.

X Q. 150. But pardon me, I just want to clear these different points up as you raise them. In your testimony where you said that a bulb properly constructed, you mean [fol. 2561] that all you have got to do is to supply more current to the filament of the structure?

A. I did not say that.

X Q. 151. That is what I am trying to get at; just exactly what do you mean by your expression?

A. That is not what I said: I was going on to tell you the rest.

By the Court:

Q. 152. Suppose you then give all of the elements.

A. Then he says at various places, as for example, page 1, line 96,

"As a very high vacuum could be obtained in the bulb and as a considerable quantity of air, and so forth——"

The two conditions are that you should be able to heat the filament to a high temperature and that you should have a high vacuum in the bulb. Now, it is true that not all bulbs, so far as I know, which have a high vacuum, and which can have the filament heated to a high temperature within the

limits of the apparatus, will oscillate, and what the critical condition that makes them oscillate is I do not know. It is a matter of the characteristic curve as to which we have comparatively little control, but by "properly constructed" I think I said in my examination exactly what I meant, namely, provided it had high enough vacuum. What I said was that all the Fleming valve bulbs, including the so-called three-element audion, exhibited before the court, have the property of "oscillating" when properly constructed—that is, if they are provided with a sufficiently high vacuum.

Q. 153. Then the only proper construction which you would require would be a sufficiently high vacuum in the bulb, to which you have added now the condition of supplying more current to the filament?

A. Yes. In other words, what I meant to say was that no special or different conditions are imposed than that imposed in constructing the bulb as a detector.

Q. 154. Let me ask you this; the higher the vacuum you have in this tube the poorer the tube will act as a generator of oscillations; is that correct?

A. I do not know.

By Mr. Darby, Jr.:

XQ. 155. I will now ask you a few questions in connection with the circuits employed along the lines of the questions asked by his Honor. It is so obvious that I do not believe it is necessary to emphasize it. The circuit employed in connection with the Fleming valve as a generator is nowhere disclosed in the Fleming patent.

A. I will be glad to operate it in that circuit if you would like.

XQ. 156. The fact that it will operate in connection with this circuit for the generation of electrical oscillations is something that has developed in the art subsequent to the Fleming invention.

The Court: That is in the circuit shown on Plaintiff's Exhibit 2.

A. The fact that it will oscillate at all, so far as I am personally concerned, is something that has been developed in [fol. 2562] comparatively recent years. That circuit is the P N circuit, and it is the circuit which is Fig. 1 of the Marconi Patent No. 627,650, I believe, which I showed in the

main case. I showed in that case that there were in that patent two circuits shown, one of which is the circuit shown in the Fleming patent and the other of which is the circuit that happened to be used with the DeForest audion box which was the subject of that litigation, and this circuit here is that circuit of the audion box but which is known as the P X circuit.

Re direct examination.

By Mr. Bull:

RDQ. 157. Will you please explain how the oscillating function of the incandescent lamp detector was discovered, so far as you know?

Mr. Darby, Jr.: If your Honor please, on that point I believe that Mr. Waterman has already testified that Mr. Weagant was the one who discovered it. Mr. Weagant is available to Mr. Bull if he cares to examine him on that point. This is secondary evidence.

The Court: He may answer.

A. The matter first came to my attention in my own use of the three-element bulbs. I was using them as detectors for the receipt of ordinary damped oscillation signals, including for example the station at Sayville, and that was the longest wave length station which my apparatus was able to receive, and I had one valve which I noticed, a three-element valve which I noticed would on a certain adjustment of the secondary condenser give a thump and immediately upon giving that thump the bulb became more sensitive and the signal came with a broken or raspy note, whereas it was characteristically a clear and musical note.

RDQ. 158. You mean the Sayville note was a clear note?

A. Yes, and I endeavored for many weeks, or over a period of time covering many weeks, to try and get the same sensitiveness without getting that peculiar note, but without success. Some time later when I was working with Mr. Weagant he explained to me that the three-element bulb was capable of acting as an oscillator and he tuned his circuits to a longer wave length than I was able to reach and immediately there came in a clear and musical signal which was the signal from an undamped oscillation station and I then recognized that what had happened was that the audion which I was using had begun to oscillate, and it was

in the use of the bulb as a detector in that way that the matter first came to my knowledge, and so far as I know also to Mr. Weagant and Mr. Armstrong.

RDQ. 159. You mean, you recognized the fact that when you got this loud and disagreeable note it was due to the fact the bulb was oscillating?

A. Yes. It is characteristic, I ought to explain, that when a damped oscillation is received with the bulb in the oscillating state, the musical note which is transmitted and which that signal would have if received by a crystal, or by a bulb in the non-oscillating setting, is changed from the [fol. 2563] pure musical note to a tone which has an aspirated sound, a whispering sound; it is broken up and ceases to be clear and musical.

When, on the other hand, a continuous wave or undamped oscillation is received by the beat method, then it is a characteristic of the oscillating valve that it gives a clear musical note. The musical note, for example, that your Honor listened to this morning is the note which is characteristic of a beat note due to the superposition of the oscillations of a different frequency, and the reason it is purely musical is because both giving continuous oscillations which differ by a definite amount, the beats are in effect sinusoidal; that is, simple harmonic, as it is called, and therefore makes a pure tone. Probably the nearest to a pure musical note of a signal that it is possible to produce in any way.

Now, when a damped oscillation is received there is no such adjustment. The valves may be oscillating, for example, at a frequency five or ten times that of the signal. Therefore, we do not have any beat effect produced, but we are merely using the valve in its ordinary way of detector plus the extra sensitiveness that comes from the oscillating condition, and so when you receive a damped oscillation one gets usually this ragged sound when the bulb is oscillating and recognizes the oscillation in that way, whereas, to receive the undamped or continuous oscillation, the beat effect has to be produced and that results in the pure musical note. And when I had my audion valve, it was a DeForest bulb, oscillate, before I knew its capacity for oscillating, it was giving this raspy note, although I did not at that time recognize it as the oscillating state and was using it as a detector, and noticed this happening, but I had not the capacity to adjust to the long wave length stations of the continuous oscillations and therefore I never myself proved

it was oscillating; Mr. Weagant did that by his ability to tune to the wave length of the continuous oscillation stations which was very long.

Of course, when it is once recognized that the bulb is oscillating, it is perfectly evident that it may be used either for heterodyne reception or as a source of oscillations for some other purpose.

RDQ. 160. Speaking from your general knowledge of the art, your expert knowledge of this art, is it or is it not true that the oscillating capacity of these incandescent lamp detectors was discovered in connection with, and directly in connection with a use as detectors of wireless waves?

A. That is the fact so far as I know, and as has always been stated and understood.

RDQ. 161. And when it was ascertained that one of these valves had the capacity for oscillating, was it or was it not obvious to one skilled in the art that that valve could be used as a generator of wireless waves?

Mr. Darby, Jr: I object to that. Objection sustained.

RDQ. 162. Have Geissler tubes ever been used in the radio art for any purpose so far as you know, either a detector or generator or anything else?

A. They have not, with the single exception that when without electrodes they have been used in experimental work to indicate nodes of wires and the like.

[fol. 2564] RDQ. 163. But not for the purpose of receiving radio signals or generating radio waves?

A. They have not so far as I know.

Re-cross-examination.

By Mr. Darby, Jr.:

RXQ. 164. In this work in which you discovered the oscillating characteristic of these vacuum tubes you were working with a three-electrode audion?

A. Yes.

RXQ. 165. And as you have previously testified, that was around 1913 or 1914?

A. That was earlier, it was before I learned from Mr. Weagant about the capacity of the valve to oscillate. I noticed this peculiar behavior and I did not know what it was, but I identified it afterwards.

RXQ. 166. In your work with the Fleming two-electrode valve prior to this discovery of oscillations with the three-electrode device you did not discover any oscillating characteristic of the two-electrode device, did you?

A. No.

RXQ. 167. In fact, the discovery of the oscillation characteristic of the two-electrode device was subsequent to your discovery and explanation by Mr. Weagant of the three-electrode device.

A. Mr. Weagant made it and my understanding is that that was the succession; it was the order in which it was revealed to me, at any rate.

RXQ. 168. It was your understanding, referring to the question asked you by Mr. Bull, that Mr. Weagant made this discovery while using the audion as a detector; is that correct?

A. Yes; all his work at that time I was familiar with was detector work; in fact, if he did not know it would oscillate he could hardly have been using it as a generator.

RXQ. 169. And as you say that was somewhere around 1914 that Mr. Weagant, or the latter part of 1913, that Mr. Weagant when using it as a detector discovered that the three-electrode valve would oscillate?

A. I said to the best of my recollection it was 1913.

RXQ. 170. Could you construct a two-electrode valve that you know would generate electrical oscillations, and by two-electrode valve I mean a two-electrode valve of the structure shown by Professor Fleming?

A. If you mean if I could construct a single valve and guarantee that it would oscillate, I do not think I could. But, of course, I personally am not skilled in the construction of those things. I never built one in my life.

RXQ. 171. In other words, you never know whether a Fleming valve structure, two electrodes, will generate oscillations until you try?

A. Well, that is not peculiar to the matter of generating oscillations. The valves are very hard to control. It is not possible in advance to tell precisely what they are going to do, whether it be acting as a detector or as a generator.

RXQ. 172. At any rate, you agree to this, that not every Fleming two-electrode structure which will act as a detector will act as an oscillator?

A. That is true as to the few that will not act to amplify; if they will amplify they will oscillate.

By Mr. Bull:

Q. 173. Let me ask you this; when one of these incandes- [fol. 2565] cent lamp detectors is being used as a detector of wireless waves, and it is in the oscillating condition, is it true that that valve at that time is acting as a generator of wireless waves?

A. It is, absolutely.

Q. 174. And as to some two-element bulbs acting as generators and others not, is the same thing true of the three-element valves?

A. So far as I know, it is; that has always been my observation.

By Mr. Darby, Jr.:

R. X Q. 175. You do not know definitely, though, do you?

A. I would not say that I do, No.

By Mr. Bull:

Q. 176. Did you ever have a three-element valve that would not oscillate?

A. Yes; I have got some now.

Q. 177. Then you do know definitely?

A. I understood Mr. Darby to ask whether one could be constructed with a certainty that it would oscillate.

By the Court:

Q. 178. Mr. Bull's question was whether you would find instances of failure to oscillate in three electrode valves just as well as in two-electrode valves.

A. There is no question about that. I have at least two made by the DeForest Company that cannot be forced into oscillations and I know that in some of those that were in evidence in this case I tried very hard to make them oscillate and did not succeed.

Q. 179. You mean in the same case?

A. I mean in the same case. There were several in the case and they were all alike; some of them oscillated and some of them did not under my manipulation; I do not know what anybody else might be able to do.

By Mr. Darby, Jr.:

R. X Q. 180. In those valves which would not oscillate, did you try them to see whether they would detect?

A. Oh, yes; they detected but they would not amplify.

Mr. Darby, Jr.: I would like to ask Mr. Weagant a question in connection with this apparatus which Mr. Waterman was not in position to answer.

ROY A. WEAGANT, a witness called on behalf of the defendant, being duly sworn, testifies as follows:

Direct examination by Mr. Darby, Jr.:

Q. 1. Mr. Weagant, do you know the amount of voltage that is employed in the oscillating circuit of the Fleming valve structure in this apparatus?

A. I think it is approximately 100 volts; I can have it measured right off, if you would like it.

Q. 2. I would like it. (Witness measures apparatus.)

A. The voltmeter shows 96 volts.

[fol. 2566] Q. 3. Are you familiar with the use of the Fleming valve structure, of the two-electrode structure, used for detection?

Mr. Bull: I object to that. I am going to try and confine this witness's examination to the condition of this apparatus and the manipulation of it and anything of that sort.

The Court: Objection sustained unless you call him as your own witness.

Mr. Darby, Jr.: I will make Mr. Weagant my own witness for the purposes of this question.

The Court: You better call him in your case.

Plaintiff's prima facie case closed.

Defendant's Proofs

ROY A. WEAGANT, recalled in behalf of the defendant, testifies as follows:

Direct examination by Mr. Darby, Jr.:

Q. 4. Are you familiar with the use of a two-electrode Fleming valve for detection purposes commercially?

A. Somewhat, yes.

Q. 5. When did you first become familiar with it for detection purposes in commercial use?

A. I do not know that I remember exactly.

Q. 6. Can you give me the approximate time?

A. It was at least earlier than 1912.

Q. 7. You cannot be more definite than that?

A. No; I do not know that I can; I do not remember particularly.

Q. 8. You do not know whether it was one or two or five years earlier than that?

A. No; I really do not.

Q. 9. Was it as much as two years?

A. I cannot say definitely because I am not sure; it may have been.

Q. 10. That is your best recollection then?

A. That is my best recollection, yes.

Q. 11. What voltage was normally used and was used in connection with the circuit of the two-electrode valve as used as a detector when you first became familiar with it?

A. I cannot be sure as to that, when I first became familiar with it. I recollect voltages of six, twelve, and I think occasionally eighteen and twenty-four, but I am not very certain about the latter.

Q. 12. Is it not a fact that the general and usual voltage used commercially is around twelve volts for detection purposes?

A. Are you referring now to the two-electrode valve and to any specific type?

Q. 13. Any type of two-electrode valve used commercially for detection purposes; I am, of course, referring to the Fleming valve.

A. I have seen the two-electrode valve used with so many voltages and over such a wide range that I am not sure I can answer your question definitely; voltages of six and twelve were very commonly employed.

Q. 14. They were the more common?

A. Yes; and I would say they were the more common, as far as I can recollect.

[fol. 2567] Q. 15. And I believe the record shows that the voltage that is employed here is about 96 volts?

A. That is correct.

Q. 16. When did you first discover that a two-electrode valve, Fleming structure, would generate oscillations?

A. I do not know that I can say; it is since 1913, but I do not definitely remember the exact time.

Q. 17. Your discovery of that characteristic of the two-electrode valve was subsequent to your discovery that the three-electrode audion would generate oscillations; is that correct?

A. It may have been, but I am not certain at this time.

Q. 18. You considered yourself to be the inventor or discoverer of the phenomenon that the three-electrode valve would generate oscillations, did you not?

A. I probably did.

Q. 19. In fact you filed an application for patent for it, did you not, claiming that particular feature?

A. Very likely; yes, I think I did.

Q. 20. And in that application you did not show a two-electrode valve, did you?

A. That I cannot say; I am quite hazy in my recollection of the application at that time.

Q. 21. I will ask you if this is a correct copy of the drawings of your application for patent disclosing and claiming the use of a three-electrode audion as a generator of electrical oscillations.

A. It evidently is one of my applications, yes, as near as I can judge from the figures.

Q. 22. You have never filed an application for the discovery that a two-electrode valve would generate oscillations, have you?

A. Yes.

Q. 23. A two-electrode valve alone?

A. Yes; I think so.

Q. 24. Are you referring to a structure where you use a three-electrode surrounding the tube?

A. No.

Q. 25. And the application which you refer to is completely independent of this application that I hold in my hand?

A. So far as I recollect. I am not certain on that because my recollection is not very definite.

Q. 26. In this application which was filed for you and in which you took the oath that you had invented the subject matter the following illustrates what you claim to be your invention, does it not?

"Means for generating electrical oscillations comprising a plurality of elements separated by a conducting gaseous medium."

A. I do not know that that was the language.

Mr. Bull: I object to that, your Honor. If he wants to ask him any questions of fact, well enough. He is reading evidently a claim which is the product of a patent solicitor. I do not see that that has anything to do with the case.

Mr. Darby, Jr.: We will offer in evidence a copy of the application as a physical exhibit. The claim that I have read is a claim as filed; it is not, as has been suggested by Mr. Bull, the wording of a patent attorney; it is what Mr. Weagant took the oath on as constituting part of his invention.

[fol. 2568] The Court: Counsel for the other side do not object to the receipt in evidence of this application; it may be marked.

Mr. Darby, Jr.: I offer in evidence the file wrapper of the application of Mr. Weagant, Serial No. 830,584, filed April 9, 1914, for "Means for generating electrical oscillations."

Marked Defendant's Exhibit A.

Q. 27. Now, for the purpose of fixing the time when you made this invention, may I ask you if you did not file an affidavit in that case in which you set forth the time you made the invention?

Mr. Bull: The application is in evidence.

Q. 28. Do you recall when you filed your application for the two-electrode valve as a generator?

A. No; I do not.

Q. 29. You do not know whether it was before or after this application?

A. I do not recall to a certainty, no.

Q. 30. That is your recollection?

A. I think it was after.

Cross-examination by Mr. Bull:

X Q. 31. You have been asked about the voltage commonly used with two-element valves. Does the voltage used have anything to do with the space between the incandescent element and the plate filament?

A. Yes.

X Q. 32. That is, the separation of those two elements?

A. Yes. The voltage used depends to a very great extent on the separation between the hot and the cold electrodes. In general, the greater you make that separation the greater is the voltage that will be used in the use of the valve as a detector.

X Q. 33. Is the separation of this particular valve which was demonstrated this morning greater or less than the separation which is ordinarily present in the commercial two-electrode valve?

A. It is quite a bit greater than is usual.

X Q. 34. If this particular valve were used as a straight detector would it not therefore require a higher voltage than one of the ordinary commercial two-electrode detectors?

A. In all probability it would, yes.

Re-direct Examination by Mr. Darby, Jr.:

R. D Q. 35. In using the Fleming two-electrode valve for detection purposes, you refer to the voltage as the battery A, or the voltage used for lighting the filament, do you not?

A. Not in any answers I have made so far, no.

R. D Q. 36. You have been using what has been called the B battery voltage?

A. I am referring to the voltage between the cold electrode and the hot electrode.

R. D Q. 37. In what respect does the spacing of the electrodes of the device employed for this demonstration differ from that employed using the two-electrode device for detection purposes?

A. Of necessity it does not differ at all; that same spacing is a perfectly good spacing for detecting purposes.

By Mr. Bull:

Q. 38. Were not these made for detectors, as a matter of fact?

A. Yes; they were.

[fol. 2569] By the Court:

Q. 39. As I understand from Mr. Waterman's testimony, this bulb with some other bulbs were on hand from some time ago?

A. Yes; that is correct.

Q. 40. That is to say, he selected some old bulbs for the purpose of the demonstration to the court?

A. Yes.

Mr. Darby, Jr.: I believe Mr. Waterman also said that he tried them and picked out those which would oscillate.

Mr. Bull: Yes.

JOHN STONE STONE, a witness called in behalf of the defendant, being duly sworn, testifies as follows:

Mr. Darby, Jr.: May I ask if you will concede Mr. Stone's qualifications?

Mr. Bull: I certainly will.

Direct examination:

By Mr. Darby, Jr.:

Q. 1. How long have you been familiar with vacuum tubes?

A. Since about 1892.

Q. 2. How long have you been familiar with the use of vacuum tubes with respect to high frequency work?

A. My first experience with vacuum tubes in high frequency work was some time in 1893.

Q. 3. Have you had occasion to make a thorough investigation and study of vacuum tubes in the various uses to which they may be put?

A. I have had considerable experience with vacuum tubes, the matter of detecting electrical oscillations and generating electrical oscillations.

Q. 4. And amplification?

A. Some.

Q. 5. You witnessed and took part in the demonstration of this apparatus that had been set up by the plaintiff I believe?

A. Yes.

Q. 6. You noticed the blue glow effect that took place in the Fleming two-electrode structure when it was as the plaintiff states generating electrical oscillations?

A. Yes.

Q. 7. Will you please describe in your own language what produced that blue glow, its effect on the circuit, and what

you can tell us in connection with the phenomenon of the appearance of that blue glow.

A. The blue glow is a phenomenon which takes place in a vacuum tube when the potential difference, or the electromotive force acting between the two electrodes, reaches such a high value as to produce a sudden decrease in the electrical resistance between those electrodes. I will not go into the scientific explanation of the mechanism that produces that sudden diminution of resistance, and will say that it is a very well recognized phenomenon, however, and amongst operators and the like, the character of users of audions and valves, it is generally spoken of as striking an arc. Personally I do not consider that the phenomenon is identical with the electric arc, but it is in the same nature an arc in so far as its effect upon the resistance of the space between the electrodes is concerned.

[fol. 2570] Q. 8. Might I ask when you say striking an arc in the colloquial, if you please, the interpretation of that, do you mean striking an arc between the electrodes?

A. Yes.

Q. 9. Might I ask is the function of that blue glow the same as the arc?

A. Functionally it seems to operate in much the same way as if a true arc were struck between the electrodes. It differs from a true arc between the electrodes only in that the diminution of the resistance which it establishes between those electrodes is not so great as would be the case if a true arc were struck between them.

Q. 10. What is the effect of that blue glow or arc on the two-electrode device for detection purposes?

A. As soon as the blue glow commences to appear in a rectifying valve, vacuum tube valve, its qualities as a rectifier, and therefore as a detector, begin to wane very rapidly, and as the blue glow increases until it finally reaches from one electrode to the other, the deleterious effect upon the detecting function of the valve becomes greater and greater until finally the valve becomes extremely inefficient or inoperative for detection purposes. And when I speak of this diminution of efficiency in the valve as a detector I do not refer to matters of small percentage, but the change is so great that a detector which may be receiving easily readable signals may cease to develop audible signals even, and a valve which is receiving quite loud signals may under the

influence of the blue glow become so inefficient that the signals become unreadable.

Q. 11. Is it possible to make a two-electrode device generate oscillations without striking that arc which you refer to?

A. So far as my experience goes, and theoretical investigation that I have made of the simple valve, or rectifier, I am convinced that it cannot oscillate unless the blue glow or so-called arc exists between the electrodes.

Q. 12. In other words, striking the arc which I believe is admitted causes the blue glow to appear, is absolutely essential and necessary for the two-electrode device to act as a generator of oscillations?

A. That is my opinion.

The Court: Then what follows from that?

Mr. Darby, Jr.: This follows, if your Honor please; it shows conclusively that you have to completely eliminate Fleming's invention to use it as a generator; in other words, the contention that it will detect is absolutely opposed to the contention that it will act for generation purposes. The minute that it strikes an arc, the minute that it generates oscillations, it absolutely ceases to rely upon its detection properties for operation.

Q. 13. May I ask if you are familiar with a similar blue glow effect in the three-electrode audion?

A. Yes.

Q. 14. Is the striking of the arc, or causing this blue glow effect to appear, necessary for the operation of the audion?

A. No; the presence of the blue glow or so-called arc militates greatly against the efficient operation of the three-electrode audion as a detector, and it also militates against its operation as an oscillion or oscillator.

[fol. 2571] Q. 15. Would the audion operate if the blue glow effect appears?

A. It begins to cease to operate effectively as soon as the blue glow appears.

Q. 16. That is what has been commonly known as paralyzing the audion, is it not?

A. Yes; the operators use that word.

Q. 17. And means have got to be taken to prevent the paralyzing of the audion or to immediately dissipate that condition as soon as it appears; is that correct?

A. Yes.

Q. 18. I believe I understood you to say that you personally knew that a two-electrode device would generate high frequency oscillations about 1893.

Mr. Bull: I object to that, if they are going into the prior art. I do not know whether that will anticipate our patent or not.

Mr. Darby, Jr.: I want to lead up to the point of when the discovery was made of the osciliation and generation by a three-electrode device as distinguished from a two-electrode device.

Mr. Bull: Ask him that question.

Mr. Darby, Jr.: I have asked that question; I wanted to be correct as to my starting point before proceeding.

The Court: Reframe the question.

Q. 19. Will you please explain how you discovered in 1893 that a two-electrode device would generate electrical oscillations?

The Court: I do not get this at all.

Q. 20. I will ask you this: when did you first obtain knowledge that the three-electrode device would generate electrical oscillation?

A. In 1912 I received that knowledge indirectly in this way; I received a letter from Dr. DeForest who was out on the Pacific Coast informing me that he had discovered that his audion would amplify alternating currents, whereupon as an old telephone engineer I wrote him a letter stating that if it would amplify telephone currents or any other currents, it would certainly oscillate, and pointed out to him what particular kind of circuits he would have to use in connection with his audion in order to prevent it from oscillating in case he wanted to do so in its use as a telephone amplifier, and I needed no further information than the fact that the audion would amplify to know that it would oscillate, nor would any other competent telephone engineer need to know anything more.

Q. 21. In what connection were the two electrode vacuum tubes that you were familiar with in 1893 used; that is, for what purpose were they used?

Mr. Bull: I object to that.

Mr. Darby, Jr.: If your Honor please, this is of the two-electrode device for generating high frequency electrical

oscillation. I want to prove by this witness that in 1893, two-electrode devices for the production of high frequency oscillation were known, and further than that, that the only difference between this device and what was known [fol. 2572] and used at that time for that purpose was that in Fleming they used a hot electrode, one electrode is heated, whereas in the old device one electrode was not heated. I want to further prove that so far as the operation of a generator of electrical oscillations is concerned, it makes no difference whether that electrode is heated or not, and further that the actual heating of the electrode is detrimental to its generation of electrical oscillations. I think that is wholly pertinent.

Mr. Bull: In the first place, I object to their going into the prior art. That is simply an effort to anticipate our patent, as I understand it. In the second place, I do not think I could have correctly heard what Mr. Stone said because my understanding is that we are here simply because Mr. Stone on the motion filed an affidavit in which he said you could not make a two-electrode device work and I think he is asking him if he did not make a two-electrode device generate way back in 1893.

The Court: Your argument as to certain proofs covered several points. I alone directed myself to one. I think any testimony which in effect is in the nature of anticipation of the state of the art prior to Fleming is not admissible in this case. Now, that is the theoretical side. Now, the practical side is this, that the books have now grown full of cases which show that certainly not in 1893 did any person have any conception of the power of generation and oscillation in its present relation; that is as certain as anything can be. A man might look back for all I know on some theoretical business about oscillations and all that sort of thing, but from the radio standpoint to go into the dark ages and the past ages to find out what happened in 1893 to my mind is utterly immaterial.

Now, on the question as to what the two-electrode will do and what a three-electrode will do, that is a different proposition. There Professor Stone's experience as a scientific man and an expert is entirely relevant along the questions which are intended to show how these things work and what in fact they do, and so on. I am perfectly clear from the testimony, I do not believe anybody disputes the fact,

that the oscillating properties or the characteristics were unknown in this relation to the scientific world until a considerable number of years after Fleming invention. As I said this morning, if the thing does oscillate, if the Fleming valve does generate, the next question is purely a question of law.

Mr. Darby, Jr.: If your Honor please, I ask you not to forget one point and that is that the plaintiff in this case is seeking to include the oscillating audion as an infringement of their patent, and to do so they have got to broaden the scope of their claims to enable them to do so.

The Court: That is a question of argument; that has got nothing to do with this 1893 proposition; I will sustain the objection.

Mr. Darby, Jr.: Exception.

Q. 22. Mr. Stone, is the heated electrode or hot electrode of the Fleming two-electrode device absolutely essential [fol. 2573] to its use as a rectifier?

A. Yes. I will say that the heating of the filament electrode in the Fleming valve is essential to its operation.

Q. 23. If the hot electrode of the Fleming valve is not heated; in other words, if the heating battery is omitted, and a sufficient voltage is employed, would the device generate electrical oscillations?

Mr. Buil: I object to that; I think it is utterly immaterial.

The Court: What is your theory on that?

Mr. Darby, Jr.: My theory is this; my next question which I intended to ask to bring it out, was if the filament was not heated, it would generate electrical oscillations more efficiently than if it were heated.

The Court: Suppose it did; then go and use one that is not heated.

Mr. Darby, Jr.: Then, of course, they would not have the Fleming invention there.

The Court: You have got one electrode that is heated; they have one that is heated. Now, you can use the finest kind of cold electrodes in the world and they do not care anything about it.

Mr. Darby, Jr.: Suppose in the three-electrode device, the hot electrode is absolutely essential for its work, whereas in the two-electrode device it is detrimental; does not that alter the situation, as a generator?

The Court: I will sustain the objection on the ground that the question is immaterial and irrelevant.

Mr. Darby, Jr.: Exception.

Q. 24. Will you examine those two circuits, Plaintiff's Exhibits 2 and 3; referring to the apparatus which those circuits, for the sake of convenience represent, you will note that an oscillating audion at the receiving end is employed, and you will further note that the receiving end is inductively coupled to the transmitting end; that is correct, is it not?

A. It is correct as to the apparatus of the demonstration but it is not shown in these exhibits as far as I can see.

Q. 25. You mean that the inductive coupling between the receiving and the transmitting is not shown?

A. Yes; that is what I mean.

Q. 26. In the receiving system the electrical oscillations are being generated, are they not?

A. Yes.

Q. 27. What effect would the electrical oscillations generated in the receiving system have upon whether or not the two-electrode device is actually generating electrical oscillations?

A. It is very difficult to say. The oscillations which are generated in the receiving circuit or the oscillating three-electrode audion, are in part due to the oscillation circuit of the two-electrode valve, and what effect that would have upon the oscillation of that circuit, or the maintenance of the oscillations of that circuit, is very difficult to say; it is impossible to say—*a priori*. The only way that I can imagine the effect of these oscillations to be determined would be to substitute a non-oscillation producing detector in a receiving circuit, and coupled with the interrupter, breaking [fol. 2574] up the train of continuous waves, and then see whether the two-electrode valve would oscillate in the transmitter without the coupling between the transmitter and the receiver.

Q. 28. What is the nature of the coupling between the oscillating audion system and the receiving system?

A. It is difficult to say what it is because the wires run back of the board, but I fancy it is a simple inductive coupling.

Mr. Bull: If you want any wires straightened out for you we will be glad to help you.

The Witness: I have examined it and find it is a simple inductive coupling between the transmitter and receiver as I had previously supposed.

Q. 29. What ordinarily is the effect of an inductive coupling between an oscillating circuit and another circuit?

A. Well, in the well known case of the grid plate circuit of the three-electrode audion, and the filament grid circuit, it is essential in causing the device to operate. A similar action might or might not take place here by the coupling between the plate filament circuit of the oscillating audion and the filament plate circuit of the two-electrode valve.

Q. 30. By the use of this three-electrode oscillating audion in this demonstration apparatus, coupled as shown by the apparatus itself, does it raise a doubt in your mind as to whether or not the two-electrode device is generating electrical oscillations of a degree sufficient to be detected?

A. No; it is undoubtedly generating those oscillations, but the coupling makes me doubt whether the two-electrode tube would oscillate in that circuit, except for the coupling with the oscillating three-electrode audion in the other circuit.

Q. 31. In other words, it raises a doubt in your mind whether this two-electrode device would generate electric oscillations without this inductive coupling with the oscillating audion at the receiving end?

A. It seems to me that that is an obvious doubt in such a structure.

Q. 32. In your opinion, Mr. Stone, do you consider this a fair test of whether or not the two-electrode device with its circuits alone would generate electrical oscillations when using a three-electrode device?

A. It is by no means so conclusive as would be a test in which there was no coupling between those circuits, and there would be no difficulty in substituting another detector for the oscillating audion and using a tone wheel.

By the Court:

Q. 33. Have you made any experiments along that line?

A. I have made a number of experiments in an effort to cause a two-electrode valve to oscillate with one of the electrodes heated to incandescence, and I have never succeeded in making it oscillate, whereas, with the tubes with both

electrodes cold and a very much higher voltage, there was no difficulty whatever in making them oscillate.

[fol. 2575] Q. 34. What effect in your opinion does the oscillating characteristic of the audion at the receiving end have on the two-element valve in its oscillation in this present connection?

A. The possible effect is due to the fact that the electromotive force impressed upon that valve is no longer, owing to the coupling, a purely direct voltage or constant unidirectional voltage; it is a uni directional voltage where the superimposed vibratory voltage comes from the oscillating audion in the receiving circuit. Moreover, the coupling is so arranged, the voltage developed by the coupling, that the oscillatory voltage produced at the terminals of the two-electrode bulb by that coupling is very much amplified by resonance in the circuit of Plaintiff's Exhibit 2.

Adjourned to March 12, 1919, at 12 m.

Trial Resumed

March 12, 1919, 12:00 m.

John Stone Stone: Resumes.

Direct Examination by Mr. Darby, Jr. (Continued):

Q. 35. Mr. Stone, have you read and do you understand the Fleming patent in suit?

A. I have and do.

Q. 36. Did you examine and did you understand the operation of the test apparatus that was demonstrated yesterday?

A. I examined the apparatus and understood its operation.

Q. 37. Will you please compare the arrangement, operation and functioning of the two-electrode valve device as shown and described in the Fleming patent with the arrangement, operation and function of the valve device used in the demonstration which was made yesterday?

A. The Fleming valve of the patent in suit as described and illustrated is included in a simple circuit, in an inductive relation with the antenna, which circuit comprises a coupling coil with the antenna and a galvanometer or other device capable of indicating the presence of a direct current in that circuit.

In the apparatus of the demonstration given in Court yesterday the two-electrode valve is connected to two branch circuits, one branch circuit comprising an iron cord impedance coil marked Z in Exhibit 2, the condenser marked C2 and a battery of approximately 95 volts potential, in addition to the telephone receiver not marked on the drawing.

The other branch circuit comprises an inductance coil marked 2 in Plaintiff's Exhibit 2, a blocking condenser marked C1 and a variable condenser marked C in that exhibit.

In the patent in suit there is no electromotive force impressed upon the two-electrode valve between the filament and grid save the minute alternating electromotive force induced in the oscillations in the antenna, and in the description contained in this patent the operation of the valve is described to be that of a simple rectifier, whereby this [fol. 2576] minute alternating impressed electromotive force is rectified and produces a small direct current in the simple circuit.

In contrast to this in the test yesterday a very large electromotive force is impressed upon the valve between its filament and plate, in addition to a very large oscillating electromotive force developed by the resonant circuit marked 2-3 by virtue of its coupling with the oscillating circuit of the three-electrode audion in the receiving circuit.

I will add here by interjection that the mode of couple employed resulted in a great magnification of the potential difference across the two-electrode valve represented in Plaintiff's Exhibit 2 by virtue of the resonant circuit 2-3 of Plaintiff's Exhibit 2. This magnification of voltage is not a small magnification, but in circuits of this type they amount to a multiplication of the impressed voltage a thousand fold.

Coming down to the disclosure of the mode of operation in the patent as compared with the mode of operation I apprehended in the apparatus of the demonstration yesterday, I find that in the patent in suit the valve is under such electrical conditions as to make it operate effectively as a simple rectifier. By contrast I find that in the test in Court yesterday owing to the presence of the large direct or unidirectional voltage due to the batery B-2 of Plaintiff's Exhibit 2 a blue glow extended from the filament to the plate, and I apprehend that under those circumstances the

action of the valve would cease to be an effective simple rectifier, but would possess different electrical properties characterized by a relatively extremely low resistance being established between the filament and the plate.

Q. 38. What elements if any do you find necessary to add to the circuits of the patent, or Fig. 1 of the patent in suit, in order to make the two-electrode valve generate oscillations, if it can be done?

A. Judging from the apparatus of the test, performed in Court yesterday, and for the sake of argument assuming that those conditions were sufficient to cause the two-electrode valve to execute sustained oscillations, I find that the elements necessarily added for this purpose are the addition of an iron cord impedance coil Z in Plaintiff's Exhibit 2, three condensers marked respectively C, C^1 and C-2, C being adjustable, a tap upon an inductance coil marked 2 in that exhibit and a battery of approximately 95 volts.

Q. 39. What is the relation of the condensers that are employed relative to the inductance that is employed in the transmitting end as illustrated in Plaintiff's Exhibit 2?

A. Calling the circuit to which you refer of the transmitting circuit the branch to the left hand of the valve in Exhibit 2, the elements are the condenser C^1, the variable condenser C and the tap on the inductance coil; also the coupling coil associated with that inductance coil in case that coupling coil was effective in producing and maintaining the oscillations in the valve in that test.

Q. 40. And in fact the variable condenser C is not shown around the inductance coil; that is correct, is it not

A. Yes; thus constituting the resonant circuit which I have referred to as 2-3.

[fol. 2577] Q. 41. Do you find any directions in the Fleming patent to add any of these elements?

A. No.

Q. 42. Do you find any directions in the Fleming patent which would make it possible to use a resonant circuit therewith, or which would direct you to use a resonant circuit in connection therewith?

A. I find no specific instructions to that effect.

Mr. Bull: I object to that; that is a matter that is for argument. We all agree as to what is in and what is not in the Fleming patent.

Q. 43. You have referred to the use of a high voltage employed in connection with tests yesterday of approximately 95 volts, as I recall the testimony of Mr. Weagant. Do you find anything in the Fleming patent which would as one familiar with the art at the date of the Fleming patent instruct you not to use a voltage sufficiently large to strike the so-called arc between the filament and the plate electrodes?

A. I do, because I find throughout the patent a description of its mode of operation as that of a rectifier or a device of uni-lateral conductivity, and as one skilled in the art I should feel that the patent directed me not to do anything that would militate against the operation of the apparatus as a rectifier.

Mr. Bull: I move to strike out the last part of that answer.

Motion granted; exception.

Mr. Bull: As a matter of fact, we are right back on the old case now.

The Court: Not only that, but this part of the testimony is quite contrary to the rule. It is perfectly all right to say that nowhere is such and such a thing, and I do not think that there is any disagreement really as to the facts between both sides, but when he starts in to say that he as one skilled in the art finds that there is in effect or by virtue of his reasons or his inferences a direction not to do something or another, that is merely argument.

Mr. Darby, Jr.: We will simply let it rest there.

Q. 44. As one skilled in the art would you say that the generation of the oscillations by the Fleming two-electrode device, if it may be made to generate electrical oscillations, would be an expected result from the directions, description and illustration contained in the Fleming patent in suit?

Mr. Bull: I object to that. Objection sustained; exception.

Q. 45. Now confining myself strictly to the functioning of the two-electrode device as shown and described in the Fleming patent in suit, the electromotive force in the plate filament circuit is an alternating electromotive force with

minute high frequency alternating voltage, I believe you stated in your answer to one of your previous questions?

A. It is.

Q. 46. And that minute high frequency alternating voltage is induced by the received radio oscillations in the antenna circuit; that is correct, is it not?

A. It is.

Q. 47. So that the result is that rectification takes place [fol. 2578] and a uni-directional current is thereby developed in that circuit?

A. Yes.

Q. 48. Is any change in that functioning of the device effected by reducing the minute alternating high frequency electromotive force by replacing the minute alternating high frequency electromotive force by a direct or uni-directional electromotive force of high voltage?

A. Yes. The functioning is completely different. In one case the alternating electromotive force acting upon the two electrodes of the device causes a rectification action to take place, resulting in a uni-directional current in the circuit. In the second case, the large electromotive force impressed upon the valve may either produce no current at all if poled in one direction, or may produce a large uni-directional current in the opposite direction, but in either case there would be no rectification.

Q. 49. You heard Mr. Waterman's testimony when the apparatus was demonstrated yesterday to the effect that he did not believe the blue glow extended between the plate and filament, did you not?

A. Yes.

Q. 50. Do you agree with Mr. Waterman's statement?

A. I do not.

Q. 51. What would be the effect on the functioning of the device if the blue glow did not extend between the filament and plate?

A. Assuming that it developed sustained oscillations when the blue glow extended between the filament and the plate in my opinion those sustained oscillations would not have been developed if the blue glow did not extend between the filament and the plate.

Q. 52. What would be the effect on the functioning of the apparatus demonstrated yesterday if the blue glow were suppressed or eliminated?

A. In my opinion the valve would become a simple rectifier and would under no circumstances develop sustained oscillations.

Q. 53. Referring again to the coupling back of the oscillating circuit, of the oscillating audion that was employed in the receiving end of the apparatus, what advantage for the test that was given in that test apparatus was secured from the arrangement employing that coupling back for the purpose of that test?

A. Owing to the fact that that coupling was made with the resonant circuit 2-3 illustrated in Plaintiff's Exhibit 2, it developed a high potential oscillating electromotive force at the terminals of the valve, and this would tend to disturb its equilibrium which might in my opinion possibly result in causing it to sustain oscillations which in its absence would not be developed.

Q. 54. Do you know of any practical use to which the arrangement employed for the demonstration yesterday with the receiver coupled back on the transmitter could be put in radio communications using the apparatus of the test apparatus on the table?

A. No. I can see no useful purpose to which it could be applied in view of the fact that the three-electrode bulb was itself developing a sustained train of oscillation which could have been used for any purpose that this apparatus was used.

Q. 55. You have heard Mr. Waterman's testimony with regard to the theory of reversibility of function; you heard Mr. Waterman's testimony?

[fol. 2579] A. I did.

Q. 56. Mr. Waterman's testimony was to the effect that the valve as a detector and rectifier is merely the reversal of the valve as a generator, or, in other words, that this is merely the phenomenon of the reversibility of function; do you agree with Mr. Waterman?

A. I do not.

Q. 57. Will you please explain that?

A. The reversible phenomena are the class of phenomena which may be best described by specific examples, as, for instance, the motor transformer which is an apparatus which when you supply it with direct current at one set of terminals will develop an alternating current in the other set of terminals, and conversely when you apply an alternating

current to the second set of terminals a direct current will be developed at the first set of terminals.

Similarly, in the case of the thermopile, if you heat one end of the thermopile, cooling the other, it will develop an electric current, and conversely if you pass an electric current through the thermopile it will heat one of these terminals and cool the other. Those are strictly reversible phenomena. But an apparatus which has been put under entirely new conditions as is the case with the two-electrode valve, assuming that it does produce sustained oscillations, in order to have it reverse its function, is not the case of the simple reversal of function; it is not a reversible phenomena that is taking place.

Cross-examination.

By Mr. Bull:

X Q. 58. I understand you to say that in this apparatus as it was operating yesterday there was present such a blue glow as would put the two-electrode valve out of action as a detector; am I right about that?

A. It would be sufficient to very greatly diminish its function as a detector.

X Q. 59. And practically put it out of commission actually as a detector?

A. Under some circumstances it would render it completely ineffective in that respect.

X Q. 60. Did you not hear this same valve with the same conditions used as a detector yesterday?

A. I do not remember.

X Q. 61. You do not remember asking Mr. Weagant to do something and Mr. Weagant misunderstood what you wanted him to do and he turned the apparatus around as we had offered to do so that the three-electrode end acted as the generator and the two-electrode end acted as the receiver?

A. I was not aware that he was doing any such thing; he may have been doing it.

X Q. 62. I was standing there and I heard him say, "Oh, excuse me, I thought that is what you wanted me to do."

A. He told me I was listening on the wrong set of telephones.

X Q. 63. You did hear something at that time?

A. I did not know what he was doing.

X Q. 64. But you did hear signals?

A. I heard a noise, it sounded to me like an arc.

X Q. 65. One of those high musical arcs?

A. Not musical; on the contrary it was just a roar.

[fol. 2580] X Q. 66. You have referred several times to the presence of an inductive coupling; you did not testify in the main case, did you?

A. No, I had nothing to do with it.

X Q. 67. Would you be surprised that precisely that same inductive coupling was used in every experiment that was made in the Court by both sides in this case?

A. I do not know what the experiments were in that case; I have not read the record.

X Q. 68. Experiments for sending and receiving; would you be surprised?

A. I could not be surprised unless I knew what the tests were and I never read the record in that case.

X Q. 69. You said that by reason of that inductive coupling you were not sure that the oscillations of the three-element valve were what were causing the two-element valve to oscillate?

A. Substantially that.

X Q. 70. And you say that notwithstanding the fact that the two valves were oscillating at different rates?

A. There appeared to be beats.

X Q. 71. There were beats?

A. Yes.

X Q. 72. Then they were oscillating at different rates?

A. I think that they were oscillating at different rates from the presence of beats.

X Q. 73. Do you think it at all probable that oscillations at one rate would set up in the other valves oscillations of a different rate?

A. I think they might very well where the oscillations produced were of the very high frequencies, and the two circuits were slightly out of tune.

X Q. 74. Is it not true that this inductive coupling which we are talking about causes the receiving circuit to abstract energy from the transmitting circuit?

A. I think it undoubtedly causes a swapping of energy between the two circuits.

X Q. 75. But you would not admit that it would cause them to abstract energy?

A. Both abstract and return.

Re-direct examination.

By Mr. Darby, Jr.:

R. D. Q. 76. You did not state in your testimony, did you, that when the blue glow occurred in a two-electrode device that that spoiled the electrode device for future use, did you?

A. No; I did not intend to imply anything of that kind.

Mr. Bull: I did not intend to imply any thing of the kind either.

Mr. Darby, Jr.: I gathered from Mr. Bull's question that on using this two-electrode device as a receiver that the inference was raised that Mr. Stone was testifying that the blue glow made it impossible for it to be used as a receiver.

Mr. Bull: I probably must apologize to my friend Mr. Darby. My scientific language was weak; my exact words were "put out of action"; I meant temporarily; I did not mean permanently.

Mr. Darby, Jr.: The file wrapper of the Fleming patent is in evidence as an exhibit, Exhibit W, in the main case. I would like also to use it in this case; do you desire it as a separate exhibit?

[fol. 2581] Mr. Bull: I think all the evidence in the main case, this is merely under a supplemental bill, all the other evidence is in this case.

The Court: There is no question about that. Let it be noted for convenience at this point that Exhibit W is the file wrapper.

Defendant's Proofs closed.

Plaintiff's Rebuttal Proofs

Frank L. Waterman, recalled in rebuttal, testifies as follows:

Direct examination.

By Mr. Bull:

Q. 181. Mr. Waterman, you heard Professor Stone say that he believed the two-element valve could not operate as a generator of wireless waves unless the blue glow was present. Does that statement accord with your experience with these lamps?

A. It does not.

Q. 182. Are you prepared to demonstrate the operation of this two-element valve to the court as a generator in the absence of the blue glow?

A. We have a bulb there which last night generated without a blue glow and again this morning. I will be glad to try and see if we can do the same thing again.

Q. 183. You have heard Professor Stone state that the presence of the three-element valve in the receiving station might have been the cause of the oscillations of the two-element valve in the generating part of the apparatus. You also heard, I suppose, Professor Stone indicate a desire to see the two-element valve operate as a generator in circuits which did not include any three-element valve; is that true?

A. I did.

Q. 184. Are you prepared to demonstrate to the court the operation of the two-element valve as a generator in circuits which do not include any three-element valve?

A. I am, with some make-shift apparatus. I tried last night to get a commercial ticker, as it is called, without success, but by the use of a file and a wire scraped over it we break up the oscillations so that they may be received with the ordinary crystal detector, that simply being a rough way of imitating the action of the ticker.

Q. 185. Did you hear me in an informal way last evening after adjournment ask Professor Stone if he happened to have a ticker apparatus in his pocket and he said he did not?

A. I did.

Q. 186. Did you also hear Mr. Weagant ask him if he would be satisfied if the demonstration were made with an ordinary file?

A. I did.

Mr. Darby, Jr.: If your Honor please, as I recall it, that is not the way the question was put to Mr. Stone. There was a qualification that Mr. Bull has not expressed.

Mr. Bull: If you will correct me.

Mr. Darby, Jr.: Mr. Stone, as I recall, stated that the file could be used in the receiving circuit in place of the inter-[fol. 2582] rupter which he expressly mentioned could be used in the receiving circuit.

Mr. Bull: I did not know anything about that. We asked him if we could use a file.

Mr. Darby, Sr.: If new tests are going to be made we ought to have an opportunity to explain them.

Mr. Bull: I suppose you will have an opportunity to explain them, but you will understand these tests are not in any sense new tests, they are tests which your Honor almost indicated yesterday his desire to see.

The Court: Yes; I did want to see it.

Mr. Bull: And we have with such other apparatus as we could get together overnight, we are prepared to show the operation.

By Mr. Bull:

Q. 187. Will you proceed to make those demonstrations, and if you can do so make them both at one time.

A. If I can get Mr. Weagant to operate the apparatus; he is familiar with it.

The Court: Mr. Weagant, will you just state for the record what you are doing?

Mr. Weagant: In this test I am going to operate the two-element Fleming valve as a generator and I am going to use the same receiving set as was used yesterday with the exception that I employ a crystal detector to detect the oscillations.

Mr. Bull: In place of the three-element valve?

Mr. Weagant: In place of the three-element valve. These oscillations, being continuous oscillations, will not make any sound in the detector unless they are broken up in some way, or unless we have the beat as we had yesterday. So I am going to break these up at the transmitter here with a file and a light piece of wire connected across the points where the key is connected in the transmitter so that that merely disturbs the oscillations that are being generated in this coil, and there will be heard in the telephone receivers a scratching corresponding to my drawing the file across, and I shall show that that scratching stops if I stop the valve, or if I throw the tuner out of tune, showing that it is due to the oscillations.

The Witness: May I make a statement? Mr. Weagant used the expression "disturbing the oscillations". That I think is not quite an apt expression of what happens. We are merely replacing the sending key by the file which makes

the interruptions at such rapidity as will correspond to a rate that the ear can obtain.

Mr. Weagant: Yes.

The Witness: There is no blue glow in the valve, if your Honor will notice.

By Mr. Bull:

Q. 188. Will you explain, Mr. Waterman, the demonstration which has just been made?

A. The demonstration is identical with that which was made yesterday, with three exceptions. The valve which is [fol. 2583] being used is a different valve and one which on account of a higher vacuum, or some characteristic that we do not know, does not require the blue glow in order to oscillate. The detector employed is an ordinary crystal detector, and the three-element valve which was employed yesterday certainly not in operation, but it has been removed from the table entirely. I may say if I may interject that the sole reason why the valve was employed as the receiver was that I apprehended that the court would desire to receive oscillations with the two-element valve as well as transmit, and that was the convenient way of doing it, and furthermore, the set is a perfectly standard regular set without modification or alteration of any kind, and, further, was immediately and readily available to bring here.

The third difference is that the oscillations, or rather the signals sent, are broken up in this instance by what is in the parlance of the art called a chopper, the file and the wire imitating the chopper. That breaking up may be done at either the transmitting or the receiving station. I have had it put where it is for two reasons. In the first place, the circuit to which it is now connected is not one which is in any way associated with the battery. Hence, it cannot by any line of argument be reasoned that the operation of the wire over the file was affecting a battery current, and that it was not the valve that was operating. The second reason was that the coil is already tapped for the purpose while the commercial apparatus which we had is not tapped for that purpose, and to connect it across a whole coil would be apt to interfere with the tuning of the coil.

The operation was as follows: Upon the lighting of the filament by merely connecting the battery to it, the two-element valve started to oscillate. Those oscillations were re-

A. Yes; that is correct.

Q. 40 That is to say, he selected some old bulbs for the purpose of the demonstration to the court?

A. Yes.

Mr. Darby, Jr.: I believe Mr. Waterman also said that he tried them and picked out those which would oscillate.

Mr. Bull: Yes.

JOHN STONE STONE, a witness called in behalf of the defendant, being duly sworn, testifies as follows:

Mr. Darby, Jr.: May I ask if you will concede Mr. Stone's qualifications?

Mr. Bull: I certainly will.

Direct examination:

By Mr. Darby, Jr.:

Q. 1. How long have you been familiar with vacuum tubes?

A. Since about 1892.

Q. 2. How long have you been familiar with the use of vacuum tubes with respect to high frequency work?

A. My first experience with vacuum tubes in high frequency work was some time in 1893.

Q. 3. Have you had occasion to make a thorough investigation and study of vacuum tubes in the various uses to which they may be put?

A. I have had considerable experience with vacuum tubes, the matter of detecting electrical oscillations and generating electrical oscillations.

Q. 4. And amplification?

A. Some.

Q. 5. You witnessed and took part in the demonstration of this apparatus that had been set up by the plaintiff I believe?

A. Yes.

Q. 6. You noticed the blue glow effect that took place in the Fleming two electrode structure when it was as the plaintiff states generating electrical oscillations?

A. Yes.

Q. 7. Will you please describe in your own language what produced that blue glow, its effect on the circuit, and what

you can tell us in connection with the phenomenon of the appearance of that blue glow.

A. The blue glow is a phenomenon which takes place in a vacuum tube when the potential difference, or the electromotive force acting between the two electrodes, reaches such a high value as to produce a sudden decrease in the electrical resistance between those electrodes. I will not go into the scientific explanation of the mechanism that produces that sudden diminution of resistance, and will say that it is a very well recognized phenomenon, however, and amongst operators and the like, the character of users of audions and valves, it is generally spoken of as striking an arc. Personally I do not consider that the phenomenon is identical with the electric arc, but it is in the same nature an arc in so far as its effect upon the resistance of the space between the electrodes is concerned.

[fol. 2570] Q. 8. Might I ask when you say striking an arc in the colloquial, if you please, the interpretation of that, do you mean striking an arc between the electrodes?

A. Yes.

Q. 9. Might I ask is the function of that blue glow the same as the arc?

A. Functionally it seems to operate in much the same way as if a true arc were struck between the electrodes. It differs from a true arc between the electrodes only in that the diminution of the resistance which it establishes between those electrodes is not so great as would be the case if a true arc were struck between them.

Q. 10. What is the effect of that blue glow or arc on the two-electrode device for detection purposes?

A. As soon as the blue glow commences to appear in a rectifying valve, vacuum tube valve, its qualities as a rectifier, and therefore as a detector, begin to wane very rapidly, and as the blue glow increases until it finally reaches from one electrode to the other, the deleterious effect upon the detecting function of the valve becomes greater and greater until finally the valve becomes extremely inefficient or inoperative for detection purposes. And when I speak of this diminution of efficiency in the valve as a detector I do not refer to matters of small percentage, but the change is so great that a detector which may be receiving easily readable signals may cease to develop audible signals even, and a valve which is receiving quite loud signals may under the

influence of the blue glow become so inefficient that the signals become unreadable.

Q. 11. Is it possible to make a two-electrode device generate oscillations without striking that arc which you refer to?

A. So far as my experience goes, and theoretical investigation that I have made of the simple valve, or rectifier, I am convinced that it cannot oscillate unless the blue glow or so-called arc exists between the electrodes.

Q. 12. In other words, striking the arc which I believe is admitted causes the blue glow to appear, is absolutely essential and necessary for the two-electrode device to act as a generator of oscillations?

A. That is my opinion.

The Court: Then what follows from that?

Mr. Darby, Jr.: This follows, if your Honor please; it shows conclusively that you have to completely eliminate Fleming's invention to use it as a generator; in other words, the contention that it will detect is absolutely opposed to the contention that it will act for generation purposes. The minute that it strikes an arc, the minute that it generates oscillations, it absolutely ceases to rely upon its detection properties for operation.

Q. 13. May I ask if you are familiar with a similar blue glow effect in the three-electrode audion?

A. Yes.

Q. 14. Is the striking of the arc, or causing this blue glow effect to appear, necessary for the operation of the audion?

A. No; the presence of the blue glow or so-called arc militates greatly against the efficient operation of the three-electrode audion as a detector, and it also militates against its operation as an oscillion or oscillator.

[fol. 2571] Q. 15. Would the audion operate if the blue glow effect appears?

A. It begins to cease to operate effectively as soon as the blue glow appears.

Q. 16. That is what has been commonly known as paralyzing the audion, is it not?

A. Yes; the operators use that word.

Q. 17. And means have got to be taken to prevent the paralyzing of the audion or to immediately dissipate that condition as soon as it appears; is that correct?

A. Yes.

Q. 18. I believe I understood you to say that you personally knew that a two-electrode device would generate high frequency oscillations about 1893.

Mr. Bull: I object to that, if they are going into the prior art. I do not know whether that will anticipate our patent or not.

Mr. Darby, Jr.: I want to lead up to the point of when the discovery was made of the oscillation and generation by a three-electrode device as distinguished from a two-electrode device.

Mr. Bull: Ask him that question.

Mr. Darby, Jr.: I have asked that question; I wanted to be correct as to my starting point before proceeding.

The Court: Reframe the question.

Q. 19. Will you please explain how you discovered in 1893 that a two-electrode device would generate electrical oscillations?

The Court: I do not get this at all.

Q. 20. I will ask you this; when did you first obtain knowledge that the three-electrode device would generate electrical oscillation?

A. In 1912 I received that knowledge indirectly in this way; I received a letter from Dr. DeForest who was out on the Pacific Coast informing me that he had discovered that his audion would amplify alternating currents, whereupon as an old telephone engineer I wrote him a letter stating that if it would amplify telephone currents or any other currents, it would certainly oscillate, and pointed out to him what particular kind of circuits he would have to use in connection with his audion in order to prevent it from oscillating in case he wanted to do so in its use as a telephone amplifier, and I needed no further information than the fact that the audion would amplify to know that it would oscillate, nor would any other competent telephone engineer need to know anything more.

Q. 21. In what connection were the two-electrode vacuum tubes that you were familiar with in 1893 used; that is, for what purpose were they used?

Mr. Bull: I object to that.

Mr. Darby, Jr.: If your Honor please, this is of the two-electrode device for generating high frequency electrical

oscillation. I want to prove by this witness that in 1893, two-electrode devices for the production of high frequency oscillation were known, and further than that, that the only difference between this device and what was known [fol. 2572] and used at that time for that purpose was that in Fleming they used a hot electrode, one electrode is heated, whereas in the old device one electrode was not heated. I want to further prove that so far as the operation of a generator of electrical oscillations is concerned, it makes no difference whether that electrode is heated or not, and further that the actual heating of the electrode is detrimental to its generation of electrical oscillations. I think that is wholly pertinent.

Mr. Bull: In the first place, I object to their going into the prior art. That is simply an effort to anticipate our patent, as I understand it. In the second place, I do not think I could have correctly heard what Mr. Stone said because my understanding is that we are here simply because Mr. Stone on the motion filed an affidavit in which he said you could not make a two-electrode device work and I think he is asking him if he did not make a two-electrode device generate way back in 1893.

The Court: Your argument as to certain proofs covered several points. I alone directed myself to one. I think any testimony which in effect is in the nature of anticipation of the state of the art prior to Fleming is not admissible in this case. Now, that is the theoretical side. Now, the practical side is this, that the books have now grown full of cases which show that certainly not in 1893 did any person have any conception of the power of generation and oscillation in its present relation; that is as certain as anything can be. A man might look back for all I know on some theoretical business about oscillations and all that sort of thing, but from the radio standpoint to go into the dark ages and the past ages to find out what happened in 1893 to my mind is utterly immaterial.

Now, on the question as to what the two-electrode will do and what a three-electrode will do, that is a different proposition. There Professor Stone's experience as a scientific man and an expert is entirely relevant along the questions which are intended to show how these things work and what in fact they do, and so on. I am perfectly clear from the testimony, I do not believe anybody disputes the fact,

that the oscillating properties or the characteristics were unknown in this relation to the scientific world until a considerable number of years after Fleming invention. As I said this morning, if the thing does oscillate, if the Fleming valve does generate, the next question is purely a question of law.

Mr. Darby, Jr.: If your Honor please, I ask you not to forget one point and that is that the plaintiff in this case is seeking to include the oscillating audion as an infringement of their patent, and to do so they have got to broaden the scope of their claims to enable them to do so.

The Court: That is a question of argument; that has got nothing to do with this 1893 proposition; I will sustain the objection.

Mr. Darby, Jr.: Exception.

Q. 22. Mr. Stone, is the heated electrode or hot electrode of the Fleming two-electrode device absolutely essential [fol. 2573] to its use as a rectifier?

A. Yes. I will say that the heating of the filament electrode in the Fleming valve is essential to its operation.

Q. 23. If the hot electrode of the Fleming valve is not heated; in other words, if the heating battery is omitted, and a sufficient voltage is employed, would the device generate electrical oscillations?

Mr. Bull: I object to that; I think it is utterly immaterial.

The Court: What is your theory on that?

Mr. Darby, Jr.: My theory is this: my next question which I intended to ask to bring it out, was if the filament was not heated, it would generate electrical oscillations more efficiently than if it were heated.

The Court: Suppose it did; then go and use one that is not heated.

Mr. Darby, Jr.: Then, of course, they would not have the Fleming invention there.

The Court: You have got one electrode that is heated; they have one that is heated. Now, you can use the finest kind of cold electrodes in the world and they do not care anything about it.

Mr. Darby, Jr.: Suppose in the three-electrode device, the hot electrode is absolutely essential for its work, whereas in the two-electrode device it is detrimental; does not that alter the situation, as a generator?

The Court: I will sustain the objection on the ground that the question is immaterial and irrelevant.

Mr. Darby, Jr.: Exception.

Q. 24. Will you examine those two circuits, Plaintiff's Exhibits 2 and 3; referring to the apparatus which those circuits, for the sake of convenience represent, you will note that an oscillating audion at the receiving end is employed, and you will further note that the receiving end is inductively coupled to the transmitting end; that is correct, is it not?

A. It is correct as to the apparatus of the demonstration but it is not shown in these exhibits as far as I can see.

Q. 25. You mean that the inductive coupling between the receiving and the transmitting is not shown?

A. Yes; that is what I mean.

Q. 26. In the receiving system the electrical oscillations are being generated, are they not?

A. Yes.

Q. 27. What effect would the electrical oscillations generated in the receiving system have upon whether or not the two-electrode device is actually generating electrical oscillations?

A. It is very difficult to say. The oscillations which are generated in the receiving circuit or the oscillating three-electrode audion, are in part due to the oscillation circuit of the two-electrode valve, and what effect that would have upon the oscillation of that circuit, or the maintenance of the oscillations of that circuit, is very difficult to say; it is impossible to say—*a priori*. The only way that I can imagine the effect of these oscillations to be determined would be to substitute a non-oscillation producing detector in a receiving circuit, and coupled with the interrupter, breaking [fol. 2574] up the train of continuous waves, and then see whether the two-electrode valve would oscillate in the transmitter without the coupling between the transmitter and the receiver.

Q. 28. What is the nature of the coupling between the oscillating audion system and the receiving system?

A. It is difficult to say what it is because the wires run back of the board, but I fancy it is a simple inductive coupling.

Mr. Bull: If you want any wires straightened out for you we will be glad to help you.

The Witness: I have examined it and find it is a simple inductive coupling between the transmitter and receiver as I had previously supposed.

Q. 29. What ordinarily is the effect of an inductive coupling between an oscillating circuit and another circuit?

A. Well, in the well known case of the grid plate circuit of the three-electrode audion, and the filament grid circuit, it is essential in causing the device to operate. A similar action might or might not take place here by the coupling between the plate filament circuit of the oscillating audion and the filament plate circuit of the two-electrode valve.

Q. 30. By the use of this three-electrode oscillating audion in this demonstration apparatus, coupled as shown by the apparatus itself, does it raise a doubt in your mind as to whether or not the two-electrode device is generating electrical oscillations of a degree sufficient to be detected?

A. No; it is undoubtedly generating those oscillations, but the coupling makes me doubt whether the two-electrode tube would oscillate in that circuit, except for the coupling with the oscillating three-electrode audion in the other circuit.

Q. 31. In other words, it raises a doubt in your mind whether this two-electrode device would generate electric oscillations without this inductive coupling with the oscillating audion at the receiving end?

A. It seems to me that that is an obvious doubt in such a structure.

Q. 32. In your opinion, Mr. Stone, do you consider this a fair test of whether or not the two-electrode device with its circuits alone would generate electrical oscillations when using a three-electrode device?

A. It is by no means so conclusive as would be a test in which there was no coupling between those circuits, and there would be no difficulty in substituting another detector for the oscillating audion and using a tone wheel.

By the Court:

Q. 33. Have you made any experiments along that line?

A. I have made a number of experiments in an effort to cause a two-electrode valve to oscillate with one of the electrodes heated to incandescence, and I have never succeeded in making it oscillate, whereas, with the tubes with both

electrodes cold and a very much higher voltage, there was no difficulty whatever in making them oscillate.

[fol. 2575] Q. 34. What effect in your opinion does the oscillating characteristic of the audion at the receiving end have on the two-element valve in its oscillation in this present connection?

A. The possible effect is due to the fact that the electromotive force impressed upon that valve is no longer, owing to the coupling, a purely direct voltage or constant unidirectional voltage; it is a uni-directional voltage where the superimposed vibratory voltage comes from the oscillating audion in the receeiving circuit. Moreover, the coupling is so arranged, the voltage developed by the coupling, that the oscillatory voltage produced at the terminals of the two-electrode bulb by that coupling is very much amplified by resonance in the circuit of Plaintiff's Exhibit 2.

Trial Resumed

March 12, 1919, 12:00 m.

John Stone Stone: Resumes.

Direct Examination by Mr. Darby, Jr. (Continued):

Q. 35. Mr. Stone, have you read and do you understand the Fleming patent in suit?

A. I have and do.

Q. 36. Did you examine and did you understand the operation of the test apparatus that was demonstrated yesterday?

A. I examined the apparatus and understood its operation.

Q. 37. Will you please compare the arrangement, operation and functioning of the two-electrode valve device as shown and described in the Fleming patent with the arrangement, operation and function of the valve device used in the demonstration which was made yesterday?

A. The Fleming valve of the patent in suit as described and illustrated is included in a simple circuit, in an inductive relation with the antenna, which circuit comprises a coupling coil with the antenna and a galvanometer or other device capable of indicating the presence of a direct current in that circuit.

In the apparatus of the demonstration given in Court yesterday the two-electrode valve is connected to two branch circuits, one branch circuit comprising an iron cord impedance coil marked Z in Exhibit 2, the condenser marked C2 and a battery of approximately 95 volts potential, in addition to the telephone receiver not marked on the drawing.

The other branch circuit comprises an inductance coil marked 2 in Plaintiff's Exhibit 2, a blocking condenser marked C^3 and a variable condenser marked C in that exhibit.

In the patent in suit there is no electromotive force impressed upon the two-electrode valve between the filament and grid save the minute alternating electromotive force induced in the oscillations in the antenna, and in the description contained in this patent the operation of the valve is described to be that of a simple rectifier, whereby this [fol. 2576] minute alternating impressed electromotive force is rectified and produces a small direct current in the simple circuit.

In contrast to this in the test yesterday a very large electromotive force is impressed upon the valve between its filament and plate, in addition to a very large oscillating electromotive force developed by the resonant circuit marked 2-3 by virtue of its coupling with the oscillating circuit of the three-electrode audion in the receiving circuit.

I will add here by interjection that the mode of couple employed resulted in a great magnification of the potential difference across the two-electrode valve represented in Plaintiff's Exhibit 2 by virtue of the resonant circuit 2-3 of Plaintiff's Exhibit 2. This magnification of voltage is not a small magnification, but in circuits of this type they amount to a multiplication of the impressed voltage a thousand fold.

Coming down to the disclosure of the mode of operation in the patent as compared with the mode of operation I apprehended in the apparatus of the demonstration yesterday, I find that in the patent in suit the valve is under such electrical conditions as to make it operate effectively as a simple rectifier. By contrast I find that in the test in Court yesterday owing to the presence of the large direct or unidirectional voltage due to the batery B-2 of Plaintiff's Exhibit 2 a blue glow extended from the filament to the plate, and I apprehend that under those circumstances the

action of the valve would cease to be an effective simple rectifier, but would possess different electrical properties characterized by a relatively extremely low resistance being established between the filament and the plate.

Q. 38. What elements if any do you find necessary to add to the circuits of the patent, or Fig. 1 of the patent in suit, in order to make the two-electrode valve generate oscillations, if it can be done?

A. Judging from the apparatus of the test, performed in Court yesterday, and for the sake of argument assuming that those conditions were sufficient to cause the two-electrode valve to execute sustained oscillations, I find that the elements necessarily added for this purpose are the addition of an iron cord impedence coil Z in Plaintiff's Exhibit 2, three condensers marked respectively C, C^1 and C-2, C being adjustable, a tap upon an inductance coil marked 2 in that exhibit and a battery of approximately 95 volts.

Q. 39. What is the relation of the condensers that are employed relative to the inductance that is employed in the transmitting end as illustrated in Plaintiff's Exhibit 2?

A. Calling the circuit to which you refer of the transmitting circuit the branch to the left hand of the valve in Exhibit 2, the elements are the condenser C^1, the variable condenser C and the tap on the inductance coil; also the coupling coil associated with that inductance coil in case that coupling coil was effective in producing and maintaining the oscillations in the valve in that test.

Q. 40. And in fact the variable condenser C is not shown around the inductance coil; that is correct, is it not

A. Yes; thus constituting the resonant circuit which I have referred to as 2-3.

[fol. 2577] Q. 41. Do you find any directions in the Fleming patent to add any of these elements?

A. No.

Q. 42. Do you find any directions in the Fleming patent which would make it possible to use a resonant circuit therewith, or which would direct you to use a resonant circuit in connection therewith?

A. I find no specific instructions to that effect.

Mr. Bull: I object to that; that is a matter that is for argument. We all agree as to what is in and what is not in the Fleming patent.

Q. 43. You have referred to the use of a high voltage employed in connection with tests yesterday of approximately 95 volts, as I recall the testimony of Mr. Weagant. Do you find anything in the Fleming patent which would as one familiar with the art at the date of the Fleming patent instruct you not to use a voltage sufficiently large to strike the so-called arc between the filament and the plate electrodes?

A. I do, because I find throughout the patent a description of its mode of operation as that of a rectifier or a device of uni-lateral conductivity, and as one skilled in the art I should feel that the patent directed me not to do anything that would militate against the operation of the apparatus as a rectifier.

Mr. Bull: I move to strike out the last part of that answer.

Motion granted; exception.

Mr. Bull: As a matter of fact, we are right back on the old case now.

The Court: Not only that, but this part of the testimony is quite contrary to the rule. It is perfectly all right to say that nowhere is such and such a thing, and I do not think that there is any disagreement really as to the facts between both sides, but when he starts in to say that he as one skilled in the art finds that there is in effect or by virtue of his reasons or his inferences a direction not to do something or another, that is merely argument.

Mr. Darby, Jr.: We will simply let it rest there.

Q. 44. As one skilled in the art would you say that the generation of the oscillations by the Fleming two-electrode device, if it may be made to generate electrical oscillations, would be an expected result from the directions, description and illustration contained in the Fleming patent in suit?

Mr. Bull: I object to that. Objection sustained; exception.

Q. 45. Now confining myself strictly to the functioning of the two-electrode device as shown and described in the Fleming patent in suit, the electromotive force in the plate filament circuit is an alternating electromotive force with

minute high frequency alternating voltage, I believe you stated in your answer to one of your previous questions?

A. It is.

Q. 46. And that minute high frequency alternating voltage is induced by the received radio oscillations in the antenna circuit; that is correct, is it not?

A. It is.

Q. 47. So that the result is that rectification takes place [fol. 2578] and a uni-directional current is thereby developed in that circuit?

A. Yes.

Q. 48. Is any change in that functioning of the device effected by reducing the minute alternating high frequency electromotive force by replacing the minute alternating high frequency electromotive force by a direct or uni-directional electromotive force of high voltage?

A. Yes. The functioning is completely different. In one case the alternating electromotive force acting upon the two electrodes of the device causes a rectification action to take place, resulting in a uni-directional current in the circuit. In the second case, the large electromotive force impressed upon the valve may either produce no current at all if poled in one direction, or may produce a large uni-directional current in the opposite direction, but in either case there would be no rectification.

Q. 49. You heard Mr. Waterman's testimony when the apparatus was demonstrated yesterday to the effect that he did not believe the blue glow extended between the plate and filament, did you not?

A. Yes.

Q. 50. Do you agree with Mr. Waterman's statement?

A. I do not.

Q. 51. What would be the effect on the functioning of the device if the blue glow did not extend between the filament and plate?

A. Assuming that it developed sustained oscillations when the blue glow extended between the filament and the plate in my opinion those sustained oscillations would not have been developed if the blue glow did not extend between the filament and the plate.

Q. 52. What would be the effect on the functioning of the apparatus demonstrated yesterday if the blue glow were suppressed or eliminated?

A. In my opinion the valve would become a simple rectifier and would under no circumstances develop sustained oscillations.

Q. 53. Referring again to the coupling back of the oscillating circuit, of the oscillating audion that was employed in the receiving end of the apparatus, what advantage for the test that was given in that test apparatus was secured from the arrangement employing that coupling back for the purpose of that test?

A. Owing to the fact that that coupling was made with the resonant circuit 2-3 illustrated in Plaintiff's Exhibit 2, it developed a high potential oscillating electromotive force at the terminals of the valve, and this would tend to disturb its equilibrium which might in my opinion possibly result in causing it to sustain oscillations which in its absence would not be developed.

Q. 54. Do you know of any practical use to which the arrangement employed for the demonstration yesterday with the receiver coupled back on the transmitter could be put in radio communications using the apparatus of the test apparatus on the table?

A. No. I can see no useful purpose to which it could be applied in view of the fact that the three-electrode bulb was itself developing a sustained train of oscillation which could have been used for any purpose that this apparatus was used.

Q. 55. You have heard Mr. Waterman's testimony with regard to the theory of reversibility of function; you heard Mr. Waterman's testimony?

[fol. 2579] A. I did.

Q. 56. Mr. Waterman's testimony was to the effect that the valve as a detector and rectifier is merely the reversal of the valve as a generator, or, in other words, that this is merely the phenomenon of the reversibility of function; do you agree with Mr. Waterman?

A. I do not.

Q. 57. Will you please explain that?

A. The reversible phenomena are the class of phenomena which may be best described by specific examples, as, for instance, the motor transformer which is an apparatus which when you supply it with direct current at one set of terminals will develop an alternating current in the other set of terminals, and conversely when you apply an alternating

current to the second set of terminals a direct current will be developed at the first set of terminals.

Similarly, in the case of the thermopile, if you heat one end of the thermopile, cooling the other, it will develop an electric current, and conversely if you pass an electric current through the thermopile it will heat one of these terminals and cool the other. Those are strictly reversible phenomena. But an apparatus which has been put under entirely new conditions as is the case with the two-electrode valve, assuming that it does produce sustained oscillations, in order to have it reverse its function, is not the case of the simple reversal of function; it is not a reversible phenomena that is taking place.

Cross-examination.

By Mr. Bull:

X Q. 58. I understand you to say that in this apparatus as it was operating yesterday there was present such a blue glow as would put the two-electrode valve out of action as a detector; am I right about that?

A. It would be sufficient to very greatly diminish its function as a detector.

X Q. 59. And practically put it out of commission actually as a detector?

A. Under some circumstances it would render it completely ineffective in that respect.

X Q. 60. Did you not hear this same valve with the same conditions used as a detector yesterday?

A. I do not remember.

X Q. 61. You do not remember asking Mr. Weagant to do something and Mr. Weagant misunderstood what you wanted him to do and he turned the apparatus around as we had offered to do so that the three-electrode end acted as the generator and the two-electrode end acted as the receiver?

A. I was not aware that he was doing any such thing; he may have been doing it.

X Q. 62. I was standing there and I heard him say, "Oh, excuse me, I thought that is what you wanted me to do."

A. He told me I was listening on the wrong set of telephones.

X Q. 63. You did hear something at that time?

A. I did not know what he was doing.

X Q. 64. But you did hear signals?

A. I heard a noise, it sounded to me like an arc.

X Q. 65. One of those high musical arcs?

A. Not musical; on the contrary it was just a roar.

[fol. 2580] X Q. 66. You have referred several times to the presence of an inductive coupling; you did not testify in the main case, did you?

A. No, I had nothing to do with it.

X Q. 67. Would you be surprised that precisely that same inductive coupling was used in every experiment that was made in the Court by both sides in this case?

A. I do not know what the experiments were in that case; I have not read the record.

X Q. 68. Experiments for sending and receiving; would you be surprised?

A. I could not be surprised unless I knew what the tests were and I never read the record in that case.

X Q. 69. You said that by reason of that inductive coupling you were not sure that the oscillations of the three-element valve were what were causing the two-element valve to oscillate?

A. Substantially that.

X Q. 70. And you say that notwithstanding the fact that the two valves were oscillati , at different rates?

A. There appeared to be beats.

X Q. 71. There were beats?

A. Yes.

X Q. 72. Then they were oscillating at different rates?

A. I think that they were oscillating at different rates from the presence of beats.

X Q. 73. Do you think it at all probable that oscillations at one rate would set up in the other valves oscillations of a different rate?

A. I think they might very well where the oscillations produced were of the very high frequencies, and the two circuits were slightly out of tune.

X Q. 74. Is it not true that this inductive coupling which we are talking about causes the receiving circuit to abstract energy from the transmitting circuit?

A. I think it undoubtedly causes a swapping of energy between the two circuits.

X Q. 75. But you would not admit that it would cause them to abstract energy?

A. Both abstract and return.

Re-direct examination.

By Mr. Darby, Jr.:

R. D. Q. 76. You did not state in your testimony, did you, that when the blue glow occurred in a two-electrode device that that spoiled the electrode device for future use, did you?

A. No; I did not intend to imply anything of that kind.

Mr. Bull: I did not intend to imply any thing of the kind either.

Mr. Darby, Jr.: I gathered from Mr. Bull's question that on using this two electrode device as a receiver that the inference was raised that Mr. Stone was testifying that the blue glow made it impossible for it to be used as a receiver.

Mr Bull: I probably must apologize to my friend Mr. Darby. My scientific language was weak; my exact words were "put out of action"; I meant temporarily; I did not mean permanently.

Mr. Darby, Jr.: The file wrapper of the Fleming patent is in evidence as an exhibit, Exhibit W, in the main case. I would like also to use it in this case; do you desire it as a separate exhibit?

[fol. 2581] Mr. Bull: I think all the evidence in the main case, this is merely under a supplemental bill, all the other evidence is in this case.

The Court: There is no question about that. Let it be noted for convenience at this point that Exhibit W is the file wrapper.

Defendant's Proofs closed.

Plaintiff's Rebuttal Proofs

Frank L. Waterman, recalled in rebuttal, testifies as follows:

Direct examination.

By Mr. Bull:

Q. 181. Mr. Waterman, you heard Professor Stone say that he believed the two-element valve could not operate as a generator of wireless waves unless the blue glow was present. Does that statement accord with your experience with these lamps?

A. It does not.

Q. 182. Are you prepared to demonstrate the operation of this two-element valve to the court as a generator in the absence of the blue glow?

A. We have a bulb there which last night generated without a blue glow and again this morning. I will be glad to try and see if we can do the same thing again.

Q. 183. You have heard Professor Stone state that the presence of the three-element valve in the receiving station might have been the cause of the oscillations of the two-element valve in the generating part of the apparatus. You also heard, I suppose, Professor Stone indicate a desire to see the two-element valve operate as a generator in circuits which did not include any three-element valve; is that true?

A. I did.

Q. 184. Are you prepared to demonstrate to the court the operation of the two-element valve as a generator in circuits which do not include any three-element valve?

A. I am, with some make-shift apparatus. I tried last night to get a commercial ticker, as it is called, without success, but by the use of a file and a wire scraped over it we break up the oscillations so that they may be received with the ordinary crystal detector, that simply being a rough way of imitating the action of the ticker.

Q. 185. Did you hear me in an informal way last evening after adjournment ask Professor Stone if he happened to have a ticker apparatus in his pocket and he said he did not?

A. I did.

Q. 186. Did you also hear Mr. Weagant ask him if he would be satisfied if the demonstration were made with an ordinary file?

A. I did.

Mr. Darby, Jr.: If your Honor please, as I recall it, that is not the way the question was put to Mr. Stone. There was a qualification that Mr. Bull has not expressed.

Mr. Bull: If you will correct me.

Mr. Darby, Jr.: Mr. Stone, as I recall, stated that the file could be used in the receiving circuit in place of the inter-[fol. 2582] rupter which he expressly mentioned could be used in the receiving circuit.

Mr. Bull: I did not know anything about that. We asked him if we could use a file.

Mr. Darby, Sr.: If new tests are going to be made we ought to have an opportunity to explain them.

Mr. Bull: I suppose you will have an opportunity to explain them, but you will understand these tests are not in any sense new tests, they are tests which your Honor almost indicated yesterday his desire to see.

The Court: Yes; I did want to see it.

Mr. Bull: And we have with such other apparatus as we could get together overnight, we are prepared to show the operation.

By Mr. Bull:

Q. 187. Will you proceed to make those demonstrations, and if you can do so make them both at one time.

A. If I can get Mr. Weagant to operate the apparatus; he is familiar with it.

The Court: Mr. Weagant, will you just state for the record what you are doing?

Mr. Weagant: In this test I am going to operate the two-element Fleming valve as a generator and I am going to use the same receiving set as was used yesterday with the exception that I employ a crystal detector to detect the oscillations.

Mr. Bull: In place of the three-element valve?

Mr. Weagant: In place of the three-element valve. These oscillations, being continuous oscillations, will not make any sound in the detector unless they are broken up in some way, or unless we have the beat as we had yesterday. So I am going to break these up at the transmitter here with a file and a light piece of wire connected across the points where the key is connected in the transmitter so that that merely disturbs the oscillations that are being generated in this coil, and there will be heard in the telephone receivers a scratching corresponding to my drawing the file across, and I shall show that that scratching stops if I stop the valve, or if I throw the tuner out of tune, showing that it is due to the oscillations.

The Witness: May I make a statement? Mr. Weagant used the expression "disturbing the oscillations". That I think is not quite an apt expression of what happens. We are merely replacing the sending key by the file which makes

the interruptions at such rapidity as will correspond to a rate that the ear can obtain.

Mr. Weagant: Yes.

The Witness: There is no blue glow in the valve, if your Honor will notice.

By Mr. Bull:

Q. 188. Will you explain, Mr. Waterman, the demonstration which has just been made?

A. The demonstration is identical with that which was made yesterday, with three exceptions. The valve which is [fol. 2583] being used is a different valve and one which on account of a higher vacuum, or some characteristic that we do not know, does not require the blue glow in order to oscillate. The detector employed is an ordinary crystal detector, and the three-element valve which was employed yesterday certainly not in operation, but it has been removed from the table entirely. I may say if I may interject that the sole reason why the valve was employed as the receiver was that I apprehended that the court would desire to receive oscillations with the two-element valve as well as trannmit, and that was the convenient way of doing it, and furthermore, the set is a perfectly standard regular set without modification or alteration of any kind, and, further, was immediately and readily available to bring here.

The third difference is that the oscillations, or rather the signals sent, are broken up in this instance by what is in the parlance of the art called a chopper, the file and the wire imitating the chopper. That breaking up may be done at either the transmitting or the receiving station. I have had it put where it is for two reasons. In the first place, the circuit to which it is now connected is not one which is in any way associated with the battery. Hence, it cannot by any line of argument be reasoned that the operation of the wire over the file was affecting a battery current, and that it was not the valve that was operating. The second reason was that the coil is already tapped for the purpose while the commercial apparatus which we had is not tapped for that purpose, and to connect it across a whole coil would be apt to interfere with the tuning of the coil.

The operation was as follows: Upon the lighting of the filament by merely connecting the battery to it, the two-element valve started to oscillate. Those oscillations were re-

ceived by the receiving set and when Mr. Weagant rubbed the fine wire over the file, the court, as I assume, heard the peculiar, raspy noise which is characteristic of the ticker type of detector, and that noise ceased when Mr. Weagant disconnected the filament, and therefore stopped the valve from oscillating. The existence of that sound was evidence that the valve was producing radio oscillations.

The fact that the valve while producing those radio oscillations was not also producing the blue glow shows what I said yesterday, that the blue glow is not a necessary accompaniment of this oscillating condition and is merely an incident to the particular valve used. The valves of this wide spacing will commonly, not always, but often show this edge glow, as I have called it, and they do not go out of action, nor do they lose their sensitiveness until suddenly a change occurs which is visible to the eye when the blue glow becomes self-perpetuating, and suddenly fills the space, and then the bulb ceases to act entirely. This is equally true of three-element bulbs and is in no way peculiarly characteristic of two-element bulbs.

Q 189. Professor Stone intimated that the condition of the blue glow which is present in the two-element valve used yesterday was the condition which rendered it either inoperative as a detector or which decreased its efficiency as a detector. Is that statement in accordance with the facts [fol. 2584] as you observed them?

A. It is not. On the contrary, the valve as used yesterday with what little evidence of blue glow there was there, was undoubtedly in or approximately in its most efficient detector condition. As a matter of fact, that apparatus could be taken and used in the oscillating state as a receiver to receive distant signals and apparatus like that was used in the demonstration to me by Mr. Weagant when he received European signals. The signals of Nauen in Germany, and as I think Professor Stone himself said yesterday, when we make beats we do not thereby detect, we merely produce something that can be detected. The beats, as Mr. Weagant said a few moments ago, themselves cannot be heard. We have to have a detecting function and that detecting function is performed by the bulb at the same time. Hence, in order that the bulb may be used, as Professor Stone used it, for example, yesterday when he listened to signals sent from the nominal receiving end, the detecting function has to be there in order that one may

receive at the time when the bulb is oscillating, and hence this oscillating condition, whether it is accompanied by this blue glow or not, not only does not destroy the detector function, nor, so far as my observation goes, impairs it in any way. On the contrary, it increases the sensitiveness of the bulb always as a detector.

When, of course, the blue glow passes the point where it is tolerable then suddenly both the detecting and the oscillating function ceases.

Q. 190. Then you distinguish between such a blue appearance which was exhibited in the two-element bulb yesterday and the true blue glow which puts a detector out of action temporarily?

A. There is a very marked distinction between them.

Q. 191. From what you have said I gather that you do not agree with Professor Stone's statement that this apparatus with the two-element valve as it stands has no commercial utility whatsoever.

A. I do disagree, and on the contrary that apparatus just as it stands when put on the big antenna could be used to receive signals from across the water.

Q. 192. Professor Stone has stated that the presence of the inductive coupling between the generating and the receiving ends of this apparatus is perhaps responsible for the fact that the two-element valve acted as a generator when the three-element valve was being used as a receiver. Will you state your views on that point?

A. I disagree with Professor Stone for three reasons. First, this coupling coil merely replaces the antenna that would ordinarily be employed in a full practical apparatus, and it is the thing which is universally used for laboratory or indoor tests. It is the same means of coupling that was used in all analogous tests in the main case and its substantial propriety was recognized by both sides throughout the case and is recognized generally in the art because it is universally employed.

The second reason why I disagree with Professor Stone is that that coil is not in any way connected with the valve that was oscillating. On the contrary, that coil connects with the primary coil in the receiving set and that is only loosely [fol. 2585] coupled to the circuit to which ultimately the three-element valve is connected. Hence it is only a feeble energy in any case which can flow in that circuit from the

valve, and it is not of a large and controlling order as might be inferred from what Professor Stone said.

In the second place, such oscillating energy as flows in that circuit, due to the oscillations of the valve, is of a different frequency from that being generated by the two-element valve acting as generator, and necessarily so, because it is the heterodyning frequency which must differ from the frequency being generated in order that beats may be produced.

Now, it is only by concurrence of impulsing that an effect such as Professor Stone referred to can be produced. The resonant effect to which he refers implies that each time an oscillation occurs an impulse is delivered strictly in time. In contradistinction to this the essence of the beat method is that that thing shall not occur, but that that shall occur successively in time and out of time so that every beat which occurs out of time tends to stop the oscillation, while every beat which occurs in time may tend to an equal amount to undue that stopping force. The net result, therefore, is zero, so far as any effect of this different frequency current on the circuit is concerned.

One aspect of the coupling that I neglected to refer to a moment ago is that the function of that coupling is to withdraw energy; that is what it is there for. Professor Stone preferred to say that they swapped energies. The energy, however, which was withdrawn was the energy produced by the two-element oscillating bulb, withdrawn at its own frequency, and therefore tended to stop the bulb from oscillating. The energy which, if we adopt Professor Stone's testimony, was swapped, was energy of a different frequency which did not tend either to stop or to make it go, the total effect was necessarily zero because of the beat phenomenon which it is its purpose to produce.

Q. 193. The circuit which is used in this demonstration apparatus has been criticised, and I am referring now to the circuit used both yesterday and today; what circuit is that; where does that come from?

A. That circuit was suggested for ti purpose by myself because it is the circuit of the DeForest apparatus that was at issue in the main case.

Q. 194. The P N circuit?

A. The P N circuit, and I supposed that that had been settled, and I just had it on that account. Also a further reason was that it was a circuit that had been dealt with

at such great length that its characteristics were made very clear. No one told me to use it, or said anything about it. I selected it myself and I am solely responsible for it.

Q. 195. As I understand it, that is the P N circuit with an impedence coil and a key added to it?

A. Yes. That is true, but the original circuit from which the P N circuit is derived had a choking coil in it. That designation P N is merely a DeForest Company's trade name. The circuit is an old well known circuit which was devised by Marconi and has been known since many years before the bulbs came into the art at all.

[fol. 2586] Q. 196. I think you referred to the Marconi patent to which you are now referring in your direct examination. To make the matter clear, I will ask if you refer to the circuit of the Marconi patent No. 627,650 which is printed at page 2669 of the printed transcript of record in this case?

A. Yes; that is what I referred to, and the iron coil, as I said, was present, as is indicated as C1, C2 in this circuit, so that in its original form the circuit included that coil.

Q. 197. Professor Stone has said that we have not here a case of true reversibility because in using this two-element valve as a generator we must change the circuits from those in which we use it as a detector; is that correct?

A. It is not. If it is going to be called reversibility at all it is certainly true reversibility because the same circuit in the same condition without alteration and adjustment, or touching it in any way, could be used to send and receive, and it was so used in this room yesterday afternoon.

Q. 198. In other words, our offer to the court was to use that same circuit in the same identical condition as a receiving circuit after we demonstrated to the court the use of it as generator circuit?

A. Yes.

Q. 199. And there was to be no alteration in the circuit whatsoever?

A. There was to be no alteration whatsoever. Furthermore, it is not necessary to call it reversibility because that action is something that occurs while you are using it as a detector, and it only requires that sort of signal known as undamped oscillation to immediately give you the beat reception whether you are looking for it or not, just as in the case where my using the three-element valve got the peculiar

characteristic of the oscillated signal, so the same thing occurs here in the use of this two-element valve.

Q. 200. In other words, as I understand you, when you are using it as a detector with the beat note the thing is generating just as truly and exactly the same way as when you are using it as a generator?

A. Yes. It takes no different manipulation of the apparatus, and if the valve is one that tends to do that, it just does it automatically.

Q. 201. It is just as truly a generator when you are using it as a beat detector as it is when you are using it as a generator?

A. Absolutely.

Cross-examination.

By Mr. Darby, Jr.:

XQ. 202. You recall Mr. Stone's suggestion of yesterday, do you not, of using a ticker or an interrupter in the receiving circuit?

A. Yes.

XQ. 203. Do you recall Mr. Weagant suggesting, or you suggesting, that you might use a file in place of it?

A. Yes.

XQ. 204. In this demonstration which you are giving now you have not done that, have you?

A. No, but we will if you want us to. The only reason it is not done is what I explained in my last answer.

XQ. 205. The principal one being you were afraid we would raise the point that the voltage was causing, or rather the current supply was causing, the click to be heard in the telephone receivers?

A. That was one reason, yes.

[fol. 2587] XQ. 206. You say you would be willing to connect it in the receiving circuit?

A. Yes.

XQ. 207. May I ask you to do it?

A. We have not the taps to do it to the same advantage, therefore it would not tune. This coil, I may say, has the special tap put in to put the sending key across. It is tapped in such a way as not to interfere with the tuning, whereas we have not this provision on this ticker.

By the Court:

Q. 208. Will this take long?
A. It might take anywhere from one minute to five or ten.

Mr. Bull: Do you want to go on with the cross-examination while they are getting that ready?
Mr. Darby, Jr.: I will be glad to do it, except I may have some cross-examination on that.
The Court: Yes.

By Mr. Darby, Jr.:

X Q. 209 Has there been any change in the amount of voltage that was employed for this demonstration today from the amount of voltage that was employed in the demonstration of yesterday?
A. I assume so; that always follows when you change valves. You always do that because you take the voltage that brings the particular valve you are using to the right point on its characteristic curve.
X Q. 210. Did you find out the approximate amount of change?
A. Yes.

Mr. Darby, Jr.: I would also like you to get that information for me; I presume that can be gotten, Mr. Weagant?
Mr. Bull: That is right; Mr. Weagant will get that.

The Witness: As I said yesterday, these valves may take anywhere from 25 to 200 volts. The amount to use is the amount that the particular valve requires.

By Mr. Bull:

Q. 211. We had some experiments relating to that, it seems to me, in the main case.
The Witness: I think we had a number.

By Mr. Darby, Jr.:

X Q. 212. Are you familiar with the use of grid oscillion?
A. I am familiar with the ordinary three-element bulbs. I have not used the large bulbs which I believe DeForest calls the oscillion.

X Q. 213. You are familiar with its use as an oscillation generator?

A. Yes.

X Q. 214. Are you familiar with its use as an oscillation generator for transmission purposes?

A. Yes, but not the bulb actually made by the DeForest Company.

X Q. 215. One of that general form including those elements in the same arrangement?

A. Yes.

X Q. 216. What voltage did you use in connection with that device, that bulb?

A. I have seen them work all the way from five or six volts up to 500 or 600, I judge; I cannot tell.

[fol. 2588] X Q. 217. In generation?

A. Yes.

X Q. 218. Of electrical oscillations for transmission purposes?

A. When you are using them for transmission purposes you choose a bulb on which you can put a high voltage.

X Q. 219. What is the voltage you generally employ?

A. I cannot say as to that, but my recollection is that on the one big bulb which I have used, which is a General Electric bulb, we used 500 or 600; it may have been 1,000, I am not certain.

X Q. 220. You have no cause to disagree with my statement, then, that the voltage generally employed with those bulbs runs from 200 to 1,500 volts?

A. That agrees with my understanding. You make a bulb with a spacing so that it will take that voltage.

Mr. Bull: Mr. Weagant is ready with his tests.

Mr. Weagant: Do you hear the scratching, your Honor?

The Court: Yes. I heard it. When the Fleming valve is put out of action the scratching noise stops. Now I hear a very faint scratching. Now the scratching is very distinct.

Mr. Bull: In the meantime Mr. Weagant was adjusting the apparatus.

The Court: Now it is thoroughly distinct.

The Witness: Will your Honor note there is no blue glow in the valve? You can get that more critically if you stand where the coil cuts the light of the filament out of your eye.

The Court: Yes, there is no blue glow as far as I can see.

The Witness: Will you please measure the voltage which you are using?

Mr. Weagant: Yes.

By Mr. Bull:

Q. 221. Will you explain the demonstration which has been made?

A. The demonstration requested by Mr. Darby has just been made. The same two-element valve was caused to send oscillations as before, but in this instance the file which was used to interrupt the oscillations was connected as requested to the receiver and the file alone was used as a ticker, as is customary in ordinary receiving practice where the ticker is employer. The bulb oscillated in this test as in the former without the production of any blue glow.

I find that the voltage employed, the measurement of which was requested by Mr. Darby, is 110 volts.

By Mr. Darby, Jr.:

X Q. 222. Referring to the Fleming disclosure in the Fleming patent, and confining yourself particularly to the disclosure in Fig. 1: Under your definition of the reversibility of function, or the phenomenon of reversibility, in your opinion would that be capable of reversible action?

Mr. Bull: I object to that; I have not asked this witness anything about the Fleming patent.

The Court: I will allow it.

[fol. 2589] A. Yes, provided that the galvanometer used is either shunted by a condenser to give a path for the oscillatory currents, or that it has sufficient capacity of itself in its own winding, as it probably would have. I assume, of course, that the question contemplates the use of the battery to provide the local source of energy.

X Q. 223. In this last demonstration that was made, Mr. Waterman, were parts of the same battery used to excite the crystal detector at the receiver and for exciting the valve at the transmitting; I do not refer to the last test, I mean the test before the last?

A. No. The crystal receiver was not connected to the battery at all.

X Q. 224. May I ask why you did not use the simple Fleming circuits as disclosed by the Fleming patent for the purposes of these tests?

A. I have already said that without giving the matter any particular thought I told Mr. Weagant to arrange his apparatus to correspond exactly to the P N circuit which was already demonstrated on various occasions before the court. I had no other reason.

X Q. 225. You had absolutely no other reason?

A. I had no other reason, no. As a matter of fact, my experience is the valve oscillates either in that circuit, or in the P N circuit, but I certainly had no reason for trying to dodge that circuit.

Testimony Closed

To be argued March 24, 1919, at 2:30 P. M.
Briefs to be submitted also.

New York, May 16, 1919.

Trial Resumed

Present: J. Edgar Bull, Esq., *Attorney for Plaintiff;* Samuel J. Darby, Esq., and Samuel J. Darby, Jr., Esq., *Attorneys for Defendant.*

Before: Hon. Julius M. Mayer, Judge.

FRANK L. WATERMAN, a witness on behalf of the plaintiff, recalled, further testifies as follows:

Redirect examination.

By Mr. Bull:

R. D. Q. 226. Mr. Waterman, at the last session you were asked the following questions and made the following answers (I read from page 58 of the record): X Q. 155: "I will now ask you a few questions in connection with the circuits employed along the lines of the questions asked by his Honor. It is so obvious that I do not believe it is necessary to emphasize it. The circuit employed in connection with the Fleming valve as a generator is nowheres disclosed in the Fleming patent?

A. I will be glad to operate it in that circuit if you would like."

[fol. 2590] Then, at page 119, on cross-examination you were asked, X Q. 222: "Referring to the Fleming disclosure in the Fleming patent and confining yourself particularly to the disclosure in Fig. 1, under your definition of the reversibility of function, or the phenomenon of reversibility, in your opinion would that be capable of reversible action?

A. Yes, provided that the galvanometer used is either shunted by a condenser to give a path for the oscillatory currents, or that it has sufficient capacity of itself in its own winding as it probably would have. I assume, of course, that the question contemplates the use of the battery to provide the local source of energy."

Now, are you prepared to make the demonstration which you expressed your willingness to make at that time?

Mr. Darby: If you Honor please, I submit this is not what we are here today for; that circuit they are going to show is substantially the identical circuit they showed at the other test, and is not the Fleming patent. I understand we are here today for a demonstration of this valve as an oscillator on the circuit of the Fleming patent. If it is merely a repetition of what was done before it is useless, and I think it appears on its face that is what it is, a repetition of what was done before.

Mr. Bull: We are getting to that, your Honor. I will show it is not a repetition of what was done before. The other was PX circuit. This is Fleming circuit. The other was a divided circuit we were talking about all through that case; this is a single circuit and not a divided circuit. It is the Fleming as distinguished from the PX circuit.

Will you please make the demonstration? (Demonstration is made.)

The Court: I hear a scratching noise as Mr. Weagant draws a fine wire across the file.

Mr. Weagant: You will notice you cannot hear that scratching device when the valve is stopped.

The Court: That is true.

Mr. Weagant: The valve is no longer lighted.

The Court: With the valve lighted I hear it again.

R. D. Q. 227. Will you please explain the experimental apparatus which has thus been demonstrated before the Court?

A. May I have the diagram, please? The experimental apparatus which is demonstrated to the Court is the same as that which was employed before with the following exceptions: The inductance coil having the iron coil and the condenser corresponding to what was removed from the circuit, and the rest of the apparatus has been rearranged so that instead of being a divided or PN circuit it is a simple series circuit such as is shown in the Fleming patent with the addition, as I stated in my former testimony, of a condenser, that is to say, the condenser C which was in the former apparatus has been preserved. The apparatus therefore is identically that of the Fleming patent as shown at the left hand side of the diagram which I produce, with the added condenser which I said would be necessary. The telephone apparatus and the coils not furnishing sufficient capacity within themselves, and that condenser being the usual accompaniment of a circuit. The actual circuit connections are shown at the right hand of the diagram where the receiving apparatus is shown. The file is used on a receiver instead of the heterodyne, because in the former tests the use of the heterodyne was objected to [fol. 2591] and the file substituted for limited tests thereon, and therefore the file has been preserved.

The Court: That is, without the condenser, as I understand it, it won't work?

A. Can you make it work without the condenser, Mr. Weagant?

Mr. Weagant: I am not sure of that. I do not think I can with this particular apparatus.

The Witness: The condenser is necessary to provide a path for the high frequency oscillations.

R. D. Q. 228. Will you point out in detail to his Honor the difference between the circuit arrangement the other day and the circuit arrangement today, because counsel has contended they are the same.

A. May I have the exhibit volume of the record? There is a diagram in there which just exactly does that. I refer to Plaintiff's Exhibit 64, found in the transcript of record, page 2455, in Marconi against DeForest.

Mr. Bull: That is this case?

The Court: Yes, this case.

A. (continuing): The circuit which was demonstrated before is that marked "DeForest Fig. 1" and which is found at the bottom of this Exhibit 64 sheet. The characteristic of this circuit is that what waves are received are impressed upon the valve used as a detector by means of one circuit through a condenser. The effect produced in the detector is recorded or made evident in a circular circuit.

Now, in the Fleming circuit, which is that shown at the top of the Exhibit 64, both of those functions are combined in one circuit. The high frequency oscillations received are impressed upon the valve in that circuit and the effect produced is registered in that same circuit, whereas in the lower figure the oscillations are registered through the upper one of the two circuits which the lower figure shows, while the effect produced is indicated in the lower one of the two circuits. That is the difference between the P N circuit and the circuit of the Fleming patent. Both of these are circuits which were shown simultaneously in Marconi Patent 627,650, and they are interchangeable circuits, that being so ever since. Their difference is in all cases we have in one instance the impression of the oscillations through a separate circuit, whereas in the simpler form of circuit which Fleming happens to show, both functions are performed in one circuit.

R. D. Q. 229. Now then, as I understand it, the apparatus which you demonstrated today is exactly like that marked "Fleming" in Plaintiff's Exhibit 64, at page 2455 of the transcript of record?

A. Yes.

R. D. Q. 230. And what you demonstrated before was like that marked "DeForest Fig. 1" in the same exhibit?

A. That is correct.

The Court: Let me ask you this, to refresh my memory: At the time of the Fleming patent was the use of the condenser as you used it today familiar to the art?

The Witness: Oh, yes, it had been familiar to the art at least three years; I think four.

[fol. 2592] R. D. Q. 231. Are you prepared to now confirm those statements by reference to literature?

A. Yes. If I may I will refer also to Plaintiff's Exhibit 12, which is the original diagram which I used in comparing the DeForest alleged infringing device with the Fleming patent. The Court will see that the same difference exists

as that pointed out by reference to Exhibit 64. In this instance the antenna happens to be shown in that issue and the wireless wave received through its effect on the coil M impresses the energy on the coil K, which is impressed by that circuit upon the valve, and what happens as a result thereof is indicated by the instrument I in that same circuit, whereas in the PN circuit the circuit which I used for demonstrating also if the valve is an oscillator, at the last hearing, we have the energy which is transported to the coil K impressed on one circuit and its effect indicated in the instrument I in another circuit. And that is the difference between those two circuits.

Now, in the circuit which I am using today the energy of the oscillation takes place in this circuit; that oscillation is tuned in the same circuit upon the valve. What happens here in this oscillating state apparently is that a disturbance produced an effect which is recorded in a change of energy here in the circuit. That change of itself is impressed again on the valve and another oscillation occurs. Each wave thus repeats. That is the way in which the oscillation apparently takes place and is preserved.

The Court: Was the tuning condenser shown in what we have often spoken of as the old Marconi circuit, referring now to Letters Patent 627,650, to Marconi?

The Witness: No, that tuning condenser in this instance is not shown.

The Court: Now, Mr. Bull suggested that we show by authority or literature this use of the condenser was known in the art at the time of the Fleming patent.

The Witness: Mr. Pickard, in this record, pointed it out at pages 336-337 of the record, and I have here quotation from his testimony which refers to Stone Patent 714,756 which I believe was in that record.

Mr. Bull: Does your Honor want that to be read in?

The Court: I think I would read it in.

The Witness: I read from page 337, folio 1010 of the record:

"In the Stone system of 1900 (Chart 35) a tune import circuit is used in which there is two condensers. One is shown as the upper condenser, which I will mark C^1 in red pencil on the chart, and the other condenser is the lower condenser, which I will mark C^2 also in red pencil on the chart. These two condensers perform different functions. One is a

tuning condenser, that is to say it has to do with the tuning of the circuit. The other is what is often in this art called a blocking condenser; that is to prevent the flow of current from Battery B over into this secondary circuit."

Referring to the Stone patent mentioned, which as appears from page 336, folio 1008, is Stone Patent 714,756, I refer to Fig. 6 thereof. In this Fig. 6 this tuning condenser is shown at C and the stopping condenser at C^1. The con- [fol. 2593] denser which I have employed is the condenser C, that is the tuning condenser, and it is connected in the same relation in the circuit as is shown in this Fig. 6 of the Stone patent, namely, effectively across this valve or detector element.

The use of this condenser was disclosed by Marconi at a very early date in his Journal of the Society of Arts paper, of May 17, 1901, and it is also disclosed in his patent which I think is in evidence in this record, 763,772, Marconi Tuning Patent as it is generally called. I refer here to Fig. 2, where the tuning condenser H^1 is shown in the same relation across the detector.

R. D. Q. 232. When was that application filed?

A. November 10, 1900. Referring to the Marconi Journal of the Society of Arts paper, I refer to page 511, near the top of the first column.

R. D. Q. 233. What is the date of that paper?

A. May 17, 1901, where Marconi says: "In order to make the tuning more moderate I place an adjustable condenser across the coherer in Fig. 9." Another instance is in Fessenden Patent 706,735, where Fessenden places a condenser in shunt to a galvanometer detector, the condenser being indicated at 19 in Fig. 1 for the purpose of permitting the free passage of oscillations and controlling the tuning. In DeForest Patent 730,246, dated June 9, 1903, the same arrangement is shown in a great many different forms. I will refer to Fig. 26, where the condenser K is shown as a tuning element in the secondary circuit. The shoemaker patent, 711,131, dated October 14, 1902, shows such arrangement in Figs. 3, 4 and 5.

I made note that Fleming in his testimony in this case, at page 141 of the record, referred to the use of a condenser. Fleming says, referring to page 141, folio 422, of the record:

"It is of course an advantage that the receiving circuit should be tuned to the wave frequency and to the transmitter frequency. The receiver circuit therefore usually contains inductance and capacity. In the simple diagram of receiving circuit figured in Fig. 1 of the specification of my U. S. Patent No. 803,684, the circuit in which the oscillation valve is placed is shown as a simple aperiodic circuit. The subject matter of that patent is, however, the nature of the wave detector itself and not of the circuits to which it is attached. It makes no manner of difference to the mode of operation of this thermionic detector in itself, whether it is connected to an aperiodic or to a tuned receiving circuit."

Professor Fleming here calls the circuit aperiodic, that is, a circuit which is incapable of sustaining oscillations. That is on the assumption that the apparatus itself does not furnish sufficient capacity, but sometimes it will. In this instance the condenser has been found apparently necessary although it oscillated with the condenser at zero, which means that the condenser has had little or no effect.

Mr. Bull: I offer in evidence the Shoemaker Patent 711,131, the DeForest Patent 730,246, the Fessenden Patent 706,735, and the Marconi Patent 763,772.

I also offer in evidence the Sketch produced by the witness, illustrating the arrangement of the circuits in the apparatus demonstrated today. The patents are marked with appropriate titles, and the Sketch is marked Plaintiff's Exhibit Waterman's Sketch, May 16, 1919.

[fol. 2594] Mr. Darby: I want to enter objection to the offer in evidence of the patents, for the reason that it is not timely, and irrelevant, immaterial, and further, it is contrary to what we understand the purpose of this demonstration, and we are therefore taken by surprise and we certainly would be entitled to rebut any evidence given in respect to these.

The Court: I will receive them and if you want to study them over, you may.

Mr. Darby: I would like to say this, your Honor, that so far we have not been favored by Mr. Bull with the data we asked for and which he promised at the hearing the other day.

The Court: I receive these in evidence in view of my own inquiry as to the state of the art at the time in regard to this

matter of the tuning condenser. Of course, if you desire an opportunity to have some time to go into that, you may have it.

Mr. Darby: It may be that the cross-examination of Mr. Waterman will supply what we want. I do not know about that. I want to reserve the point.

The Court. All right; proceed.

R. D. Q. 234. Have you any other patents illustrating the same point?

A. I have a considerable number of other patents to Stone. These are 714,831, dated December 2, 1902, where I refer for example to Fig. 5.

R. D. Q. 235. Which shows tuning condenser where?

A. It shows tuning condenser at C.

R. D. Q. 236. Now, if you will, just go through each one of those, saying that.

A. Stone Patent 716,136, dated December 16, 1902, where the condenser is shown at C in the figure.

Stone Patent 717,514, dated December 30, 1902, where the condenser is shown at C in Fig. 3.

Stone Patent 725,634, dated April 14, 1903, where the tuning condenser is shown at C in Fig. 9.

Stone Patent 725,635, April 14, 1903, where the condenser is shown at C in Fig. 2.

Stone Patent 725,636, where the condenser is shown at C, in Fig. 3.

In citing these figures I do not cite them as the only instances where such tuning condenser is shown in these patents but merely take a figure as illustrative.

R. D. Q. 237. Mr. Waterman, can you now demonstrate the oscillation of this apparatus with the condenser disconnected?

(Witness demonstrates.)

The Court: I hear a scratch on the file distinctly.

The Witness: The condenser is now disconnected.

Mr. Bull: That is all.

Recross-examination.

By Mr. Darby, Jr.:

R. X Q. 238. I understood you to say, Mr. Waterman, that Fleming, the inventor, states that the circuit of his path is

aperiodic and consequently it is not oscillatory, is that correct?

A. I quoted what he said.

R. X Q. 239. That is correct substantially?

A. I may say whether such a circuit is or is not aperiodic [fol. 2595] depends upon the apparatus that is used. If the apparatus itself has sufficient capacity and sufficient lower resistance then it is oscillatory, and that proves to be the case here.

R. X Q. 240. That is merely incidental though, is it not?

A. That is usual. As a matter of fact such circuits used to be called aperiodic, but it is the usual thing to find them oscillatory, but it is not necessarily true that even if oscillatory they will have energy storage capacity enough to sustain oscillations in the valve because such oscillations imply that the circuit shall have some energy storage capacity that is appreciable as compared to the sensitiveness of the valve.

R. X Q. 241. The oscillations produced by this valve without the condenser are not of sufficient strength for any commercial purpose of transmission, are they?

A. In that particular apparatus probably not, no. It was not made for that purpose. That valve is a very small valve, made for detector purposes.

R. X Q. 242. Then you have taken what Fleming has called an aperiodic circuit and have made it an oscillatory circuit by merely controlling the capacity and inductance of the circuit, is that true, or have you added something in addition?

A. I have neither added anything nor have I controlled the constants of the circuit. The coil is just an ordinary wireless coil, such as has always been used; and an ordinary telephone is substituted for the galvanometer which Fleming shows.

R. X Q. 243. Can you make this valve oscillatory without the B Battery?

A. Certainly not.

R. X Q. 244. Is the B Battery shown in the Fleming Patent?

A. No, the B Battery is not shown in the Fleming patent, but that I assume has been sufficiently thrashed out in this case.

R. X Q. 245. Not for the purpose of transmission. Then you have in fact added an element to the Fleming circuit which is not shown in the patent?

A. Absolutely, I have added the battery. That I said in my former testimony.

Re-redirect examination.

By Mr. Bull:

R. R. D. Q. 246. Did you ever suggest, Mr. Waterman that you could with one of these valves generate current if you did not have any current to oscillate?

A. I certainly did not.

R. R. D. Q. 247. Or cause oscillations, rather, if you did not have any current to oscillate?

A. I certainly did not. There must be a source of energy. There must be a cold wire energy when you generate energy in your electric wires.

R. R. D. Q. 248. And that is what you specifically pointed out in answer to Mr. Darby's question at the last hearing, when he asked you if this circuit could be made to generate oscillations?

A. I did.

Re recross examination.

By Mr. Darby, Jr.:

R. R. X Q. 249. Is not the A Battery a source of energy for reception purposes?

A. For heating the filament prone only.

Mr. Darby, Jr.: For the sake of the record, I would like to have it noted that the B Battery employed is 150 volts.

R. R. X Q. 250. Are these the same valves, do you know, that were used at the last demonstration, or have they been constructed since that time?

A. Well, I know the valves that were used in the last demonstration are here.

[fol. 2596] R. R. X Q. 251. Are here?

A. Are here also; all; which one is used I do not know, but I do know, that is, I understand, that they have not been constructed since the last demonstration.

Mr. Darby, Jr.: Mr. Weagant, is this particular valve that was employed in the demonstration constructed since the last demonstration, or has it been altered in any way?

Mr. Weagant: No. They are all of the same lot. They were made two or three years ago.

The Court: Mr. Waterman seems to think even more than that.

The Witness: It is so long ago that I really forget just when.

The Court: They were just that lot of valves which you spoke of before; they were taken from what you have?

Mr. Weagant: Yes.

Mr. Darby, Jr.: I would like to ask Mr. Weagant; Mr. Weagant can probably tell us, if this particular valve is one that was refitted for detector purposes?

Mr. Weagant: I can say that it is not.

Mr. Darby, Jr.: It is not one that was refitted for detector purposes?

Mr. Weagant: It is not.

The Witness: There is one thing I think might appear on the record in connection with the fact that the voltage is 150, and that is this valve is one of very long spacing, fully $^3/_4$ of an inch between the nearest point of the filament and the plate, and as I explained at the last hearing, the voltage which is employed could not fag; and the lot of valves which Mr. Weagant and I were experimenting on when this was made was with that spacing.

Mr. Darby, Jr.: If your Honor please, I do not like to burden you with continued demonstrations or anything of that nature, but what I did want to show was this, and I do not know whether you would be interested in it or not, and if you are not interested in it we will drop it, but the Fleming patent calls for a valve containing a very high degree of vacuum. I am prepared to demonstrate if they keep this valve in the condition it is now that that valve is a low vacuum valve, and that if it is made of a high vacuum valve they cannot make it oscillate. It is true that it is a question of degree between the high and the low vacuum, but Fleming has put himself on record what he meant by high vacuum. He has done so again recently, in 1916, what he meant by high vacuum as used in his patent at that time.

Mr. Bull: We do not care what he meant by it.

The Court: Under well settled principles of the patent law, he is not the one to whom we have to refer.

Mr. Darby, Jr.: What was meant by him at the time the patent was drawn up?

The Court: It is a simple and well settled proposition that we do not get the man's own construction of his patent. If you did, why, every man who patented something would be sure to have a valid patent.

Mr. Darby, Jr.: Well, you will recall there were some letters offered by the plaintiff as exhibits on this question. [f. 2597] Mr. Darby: It is not a question of construction of the patent, it is a question of the physical structure.

The Court: I do not see that we gain anything by that at all.

Mr. Darby, Jr.: Except this, in the one instance they have got a high vacuum which is of high resistance across that path and in the other instance to have it control it at all they have to have a low resistance across that path.

A lot has been said about the condenser. We did not bring that up.

Mr. Bull: Excuse me, your father did if you did not.

Mr. Darby, Jr.: On the condenser?

Mr. Bull: Yes, the very first thing you said was about the condenser to me.

Mr. Darby, Jr.: In the trial?

Mr. Bull: Off the record.

Mr. Darby, Jr.: I mean on the record. I have not brought up the question of condenser at all because that is not the point on which we are relying. We accepted at the start Mr. Waterman's statement when the distribution capacity is sufficient you could make it oscillate provided you put in a B Battery and provided you have a gasless medium in there or other low degree vacuum absolutely contrary to what is called for by the Fleming patent, and I think the B Battery situation has taken care of itself.

We are prepared to make any test to show that with the degree of vacuum called for by the Fleming patent they could not make it oscillate even with the B Battery.

Mr. Bull: As to the degree of vacuation, I do not see what it has got to do with it, but I am prepared by Mr. Waterman to have him state what kind of vacuum that has got in it, if he knows.

The Court: Do you know, Mr. Waterman?

The Witness: I know, from the way it behaved.

The Court: What is your judgment?

The Witness: The filament was run during these adjustments at temperatures that are exceedingly high for even a tungsten filament, which temperatures are enormously higher than the carbon filament which Fleming's could have been run at. It had 150 volts on the space, and under none of these conditions was there a blue glow. That indicates a vacuum which is of very high order, probably of an order very much superior to anything that could have been obtained as a matter of physical fact in Fleming's day, so that it probably has not only Fleming's vacuum, but one very much higher than Fleming could have gotten.

Mr. Darby, Jr.: We are prepared to make an accurate measurement of that bulb, and with regard to its being of higher vacuum, it is a physical and scientific impossibility. I am informed by engineers that valve would not oscillate with 150 volts; it is a scientific impossibility, if it has a high vacuum.

The Court: I think your proposition is very simple. You have here the hot and cold electro device of Edison?

Mr. Darby, Jr.: Yes, sir. Now, in the course of description Fleming refers to a high vacuum, which is a relative [fol. 2598] term. Now they take one of these Edison electric bulbs and in connection originally with the detector Fleming made this invention by demonstrating that he could use this Edison device in certain relations and make the thing detect radio signals. Now then, they take for all practical purposes the same thing and insist that it can generate oscillations as well as detect. I do not think they insisted all of them could do it; about one per cent.

Mr. Bull: No; I pointed out at the last argument it was absolutely not so at all.

Mr. Darby, Jr.: He further testified he can not take any one of these bulbs, build one, and be sure it is going to oscillate.

The Court: You mean in the relation shown strictly in the Fleming patent?

Mr. Darby, Jr.: Yes, sir. That is, it is an idiosyncrasy.

The Court: If this experiment is true they have demonstrated that it can be done.

Mr. Darby, Jr.: In certain circuits, yes.

Mr. Darby: 150 volts is comparable with the voltage employed for different purposes.

The Court: My point is, that whatever the controversy is and the points of difference between the litigants, that the controversy is well exposed. I do not see that I will gain anything by an experiment which takes different bulbs and maybe gets a lesser result. Now, probably they would try 20 bulbs and maybe two of them would do the thing without the condenser and the 18 might not, for all I know.

Mr. Darby, Jr.: For the sake of the record, the experiment I wanted to make is this: Take any bulk and show where it will oscillate and show where it stops to operate. As I stated at the outset, you may not be interested.

The Court: Revolving on the question of high vacuum?

Mr. Darby, Jr.: Yes. What is high vacuum? Using Fleming's own statement, even of 1916, and even today when a man skilled in the art saw and read the words "high vacuum", what would he understand? The high vacuum obtainable, and then see what was the highest vacuum obtainable at that time, which is pretty nearly the same degree they can get now. I think that shows pretty nearly in the art.

Mr. Bull: You were not in the main case or you would have heard your brother counsel argue there——

The Court: Brother-father counsel.

Mr. Bull: Yes. That the vacuum of the Fleming patent was not any vacuum at all; it was all gas; they said it was full of gas.

The Court: In the main case the vacuum referred to was the vacuum of the order of an incandescent electric lamp. Now that being so and the case having been there fully considered both by this court and the Circuit Court of Appeals, upon that together with other matters, I do not see that on this question we gain anything at all by further experiment on the line indicated by you.

Mr. Darby: Could we, if your Honor please, along that line ascertain just what the vacuum is in the lamp that was tested?

The Court: I do not see any objection to that. Can you measure that now, or do you have instrumentalities?

[fol. 2599] Mr. Darby, Jr.: We have to have instrumentalities to measure it. I think if Mr. Bull and I can agree on some mutual third party to take charge of the valve and have it tested, we can have it done that way.

The Court: What kind of test do you have to make?

Mr. Bull: Mr. Weagant says they can never agree as to what the result was after it was measured: in other words there is no accurate method of determining from the outside what vacuum there is on the inside.

The Court: Let me ask you this, Mr. Waterman: this, as I understand, is a normal type of an incandescent lamp? Is that so?

The Witness: Absolutely.

The Court: And is fundamentally known and at all times has been known in the art as such?

The Witness: Yes.

The Court: With a vacuum?

The Witness: Yes, and the vacuum we are using is high for incandescent lamps; that is, they were of the best, and we tested the highest point voltage they would stand without beginning to produce a blue bulb and with the high temperature filament.

The Court: I do not see that we can gain anything, Mr. Darby.

Mr. Darby, Jr.: All right, sir. Are we to file briefs or memoranda?

The Court: Yes, I wish you would give me a memorandum practically on two points. I mean I do not confine you to that: if there is anything occurs to either of you you may add.

Point No. 1: Whether the use of the Battery B current in any manner affects the proposition of law which the plaintiff advances, that is to say, whether the use of that Battery B device, which was not shown in the Fleming patent, has any legal effect upon the comprehensiveness of the patent. Do you understand the point?

Mr. Darby, Jr.: Yes, sir.

The Court: Now then, the second point is: Assume for the purpose of the argument that the oscillating qualities of the Fleming valve when shown in the Fleming circuit without the condenser and even with the Battery B current is only occasionally perceptive, and assume further that the Fleming valve when used in the old Marconi circuit or in any other relation of circuits then known to the art does in point of fact clearly and plainly oscillate, then as applied to the oscillating qualities as distinguished from the detecting ones, may the plaintiff in seeking to have its present construction of the patent obtain, have the advantage of the situation of the Fleming valve with existing circuits

known to the art other than the circuit shown in the Fleming patent? Do you understand?

Mr. Bull: I think we do.

The Court: In other words, to explain that a little, when Fleming made this invention, which I held and the Circuit Court of Appeals sustained me, was a very marked advantage and a very meritorious invention for detecting wireless signals at a time when neither he nor any other scientist understood or appreciated that the same instru- [fol. 2600] mentality could generate wireless waves, must the patent be held within the strict limits of its physical disclosures, the diagrams and the words, or may it go to the point of taking in any result which was obtainable by using precisely that same device with other well known circuits? Now, there is the whole case.

Mr. Darby, Jr.: How about the time?

The Court: Anything that is within reason.

(Briefs to be submitted June 3, 1919.)

UNITED STATES DISTRICT COURT, SOUTHERN DISTRICT OF NEW YORK

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA,
Plaintiff,

against

DEFOREST RADIO TELEPHONE & TELEGRAPH COMPANY,
Defendant

MEMORANDUM OF MAYER, D. J., HOLDING "AMPLIFIERS" WITHIN ORIGINAL DECREE—Filed July 11, 1917

This is the return of an order to show cause why the decree and injunction heretofore made and issued do not cover and include certain devices which defendant makes and sells and why the reports already filed should not be extended to include such devices.

The devices in question are called "amplifiers" and "oscillions."

In the first place, this procedure is correct. It has frequently been followed in this Court and, as I understand, approved by the Circuit Court of Appeals.

The opinions of the Circuit Court of Appeals and of this Court on the main controversy so fully discussed the essential features of the patent and the infringing devices that it must be assumed that the litigants are, by this time, fully informed of the views of the two courts. As in the original case, there is again the use of "audion" language which is more or less meaningless from the standpoint of the patent law and certainly does not add to a clear understanding of what has now become reasonably simple, even in an abtruse art.

1. An amplifier consists really of two or more detectors in tandem with a telephone transformer interposed between each element of the series. The primary element of such an amplifier may be either an audion or any other form of detector. In some of the amplifier sets sold by defendant [fol. 2001] ant, the primary element is a part of the outfit. In other instances, the primary element is not part of the outfit. (See Exhibit E, J. 2.)

I fully agree with Waterman on his facts and explanation as to the "amplifiers." In other words, an "amplifier" is part of a detector. In any event, the case falls under the familiar rule of *Bobbet v. Enos*, 91 U. S. 150, 457, many times since reiterated and followed. I have no doubt whatever that the motion in this regard must be granted.

2. I am not clearly convinced that the Fleming valve can perform the functions of an "oscillion" so as to oscillate and generate radio waves. On this branch it will be necessary to give demonstrations or oral testimony, or both, and witnesses should be subject to cross-examination. This is really equivalent to a trial. My view is that where the court on an application of this kind is not clearly convinced that the motion should not be granted, then the proceeding should be by bill and answer because the inquiry necessarily develops into a trial and, therefore, the issue should be clearly joined. There is usually little saving of time or labor in short cuts.

The motion, therefore, as to "oscillions" is denied.
Submit order on two days' notice.
July 11, 1917.

Julius M. Mayer, District Judge

United States District Court, Southern District of New York

Marconi Wireless Telegraph Company of America, Plaintiff,

against

DeForest Radio Telephone & Telegraph Company, Defendant

Opinion of Mayer, D. J., Holding "Oscillations" Interpolements. Filed July 7, 1919

J. Edgar Bull and L. F. H. Betts, of New York City, for Plaintiff.

Samuel E. Darby and Samuel E. Darby, Jr., both of New York City, for Defendant.

Final hearing on supplemental bill.

Mayer, District Judge:

The Fleming patent No. 803684, so far as concerned a [Fol. 2602] detector for radio waves, was fully discussed in *Marconi v. DeForest*, 236 Fed. Rep. 942; affirmed 243 Fed. Rep. 560.

The effect of the decision *supra* of this court, as affirmed by the Circuit Court of Appeals, *supra*, was to accord to Fleming's invention a high place in the art.

Eight or nine years after the date of the Fleming patent — the exact dates are unimportant — Armstrong, Hogan, Waterman, Weagant and probably other experts in the radio art, while using these devices as radio wave detectors, independently observed that the detectors possessed the function of oscillating or, in other words, of generating radio waves. This was an extraordinary additional property or function of the so-called incandescent lamp detector of which Fleming had no knowledge.

Claim 1 of the patent in suit read:

"1. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for heating one of the conductors, and a circuit outside the vessel connecting the two conductors."

While the claim covers broadly the device when used in the radio art, yet when read with the context of the specification, it is plain that Fleming's disclosure was addressed to use of the instrumentality as a detector only.

It is, however, a principle of the patent law—so well settled as not to call for citations of authority—that a patentee is entitled to all of the benefits of his invention whether or not known to or foreseen by him.

Thus, the first inquiry is whether the Fleming valve, as disclosed by the patent, will oscillate when used in circuits and with instrumentalities available as of the Fleming date and of the kind and character which, upon the evidence, it would be assumed would or could have been used as of that date.

The testimony of the experts and numerous demonstrations in the court room (some required by the court by way of extra caution and assurance), proved beyond peradventure that the two element valve possesses inherently the same capacity for generating radio waves as is possessed by defendant's three element device.

The only question in this connection is whether plaintiff, in order to hold this feature of the Fleming invention, may use a battery.

Obviously, the Fleming valve cannot oscillate unless a battery is used; but, to use a battery would, of course, not involve invention, once it is determined that the Fleming valve possesses inherently the ability to generate radio waves.

As counsel for plaintiff aptly say, "one might as well ask whether a boiler could be made to generate steam without a fire under it or whether a dynamo could be made to generate electricity without an engine to drive it."

Indeed, on this branch of the case, the question is whether, in order to make the Fleming valve oscillate, anything need be done or added which would amount to invention. As the answer to this inquiry is plainly in the negative, one necessarily returns to the proposition that as Fleming gave the art a new instrumentality, and as that instrumentality [fol. 2003] without inventive changes or additions will oscillate as well as detect, he is entitled to this feature although unknown to him.

The next question is: If the two element valve will certainly and reliably oscillate in common and well-known detector circuits of Fleming's day (Marconi or PN circuit), but will not certainly and reliably oscillate in the precise circuit shown in the Fleming patent without a condenser, is Fleming entitled to the benefits of the device as a generator of oscillations?

The valve was made to oscillate without a condenser although the action in this regard is not certain and reliable; but, this latter fact is immaterial.

The main case has really disposed of this point because this court and the Circuit Court of Appeals have held, inter alia, that Fleming's contribution was the device per se, which could be used in any circuits and with any instrumentalities then known to the art.

Bell Telephone Case, 126 U. S. 1.

Indeed, the case on analysis is much simpler than when first presented.

On preliminary impression there is reluctance to extend the patent to an unexpected characteristic only observed after a considerable lapse of time by the highly skilled men who are students in the art.

Yet, after all, it was Fleming who made this remarkable contribution of a wholly new device which, of itself, and its development has done so much toward the practical advance of this great art.

The case is fully as meritorious as Western Electric Company vs. La Rue, 139 U. S. 601, 605, which, as nearly as may be, presented an analogous question.

Under the authority of that case it is clear that where there is a capacity of reversibility with the same instrumentality, the courts will not restrict the claim to one attribute to the exclusion of the reversible attribute; and, for that matter, this case is stronger than the La Rue case because Claim 1 supra is broadly for the instrumentality.

It is concluded, therefore, that the so called oscillation of defendant intringes and that the decree heretofore filed should be extended thereto with costs.

Submit decree accordingly not later than July 11, 1919.

Julius M. Mayer, District Judge.

July 7, 1919.

[fol. 2604] At a stated term of the United States District Court for the Southern District of New York, held in the United States Court Rooms, in the Borough of Manhattan, City and State of New York, on the 9th day of July, 1919.

Present: Hon. Julius M. Mayer, U. S. D. J.

In Equity No. 12-31. On Fleming Patent No. 803,684

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA,
Plaintiff,

vs.

DEFOREST RADIO TELEPHONE & TELEGRAPH COMPANY,
Defendant

This cause having come on to be further heard on the supplemental bill of complaint and answer and proofs taken and filed on behalf of both parties herein and counsel for the respective parties having been heard and due consideration having been had, it is, upon motion of Sheffield & Betts, Solicitors for the Plaintiff,

Ordered, adjudged and decreed that in addition to the devices or apparatus heretofore manufactured and sold by the defendant and decreed to be an infringement of claim 1 of the Fleming patent No. 803,684, in suit, the devices or apparatus called by the defendant "oscillions" which have been manufactured and sold by the defendant separately, as well as the devices or apparatus which the defendant has manufactured and sold comprising "oscillions" alone or in combination with other apparatus or instruments are infringements of said claim 1 of the said Fleming patent in suit; and that any bulbs embodying said claim 1 manufactured and sold by the defendant for use in such "oscillions" or combination of "oscillions" and other instruments or apparatus, are also an infringement of said claim 1, of the said Fleming patent in suit; and that the injunction ordered to issue out of and under the seal of this Court by the Interlocutory Decree of October 9, 1916, and said Interlocutory Decree shall cover and include each and all of such devices or pieces of apparatus and that the defendant shall account to the plaintiff for all damages and profits to which the plaintiff may be entitled by reason of such infringing manufacture and sale as provided for in said Decree of October 9, 1916.

And it is further ordered, adjudged and decreed that the plaintiff, Marconi Wireless Telegraph Company of America, do recover of the defendant, DeForest Radio Telephone

[fols. 2605-2606] and Telegraph Company, the costs and taxable disbursements in connection with said supplemental bill of complaint herein and the trial thereunder.

(Sgd.) J. M. Mayer, U. S. District Judge

It is hereby consented that the above order may be entered without further notice.

(Sgd.) Sheffield & Betts, Plaintiff's Solicitors: (Sgd.) Darby & Darby, Defendant's Solicitors.

SOME FACTS ABOUT THE DE FOREST RADIO TELEPHONE AND TELEGRAPH

Compared with the ordinary wireless telegraph, the Radio Telephone can transmit from five or ten times as many words per minute.

As regards its ability to work through adverse interference, static disturbances, etc., the Radio Telephone is actually superior to the Wireless Telegraph. The British Admiralty Tests demonstrated this particularly. Such a percentage of accuracy, for example, as that of only two errors out of a list of 154 numbers (some of five and six figures) as a distance of 50 miles, through severe interference, would have been impossible by means of the spark telegraph.

To replace flag-signalling at sea the Radio Telephone, calling off merely the numbers of the code signals used, has clearly demonstrated its great merit, and this for distances ten times those possible by visual signalling, through fog, smoke, or foul weather, by night as well as day, and with a hundred fold greater speed.

The apparatus is thoroughly reliable. When once properly installed and adjusted, it is simply necessary to turn on the power and throw the transfer switch to one position for talking and to the other for listening.

The transmission of speech is perfect. It is at least as clear and distinct as that over a wire telephone line if not more so.

The experiments conducted at the naval station at Arlington (Washington, D. C.), whereby speech was transmitted to Paris, San Francisco and Honolulu, were carried out on this same system, under license of our patents. This speaks volumes for the range and clearness of speech.

The apparatus is compact and comparatively inexpensive, both from the standpoint of initial and operating costs.

Where electric power is available, the Radio Telephone Set is operated from it by means of a motor generator furnished. The consumption of power is low and entirely within the capacity of any standard electric lighting plant.

Where no electric power can be obtained, a small gasoline engine is furnished, connected to a generator either directly or by belt.

APPLICATIONS

For yachts and house boats. The Radio Telephone enables the captain or owner to talk to the home, club house or to other craft, saving time and obtaining an instant reply.

For all classes of commercial ships, barges, tugs and lighters. The captain can be in touch with the office and passing ships. No special operator is needed.

For intercommunication between islands and with the mainland, e.g., along the Carolina and Florida Coasts, in Delaware and Chesapeake Bay, the Thousand Islands, etc., the apparatus is now available.

For Revenue Service, coast and inland Surveys, Forestry, etc., the Radio Telephone has a large field.

For connecting offices and factories where wire telephone tolls are excessive or service unreliable.

For emergency or regular service by electric transmission companies to insure communication between generating and sub-stations and switching points at all times.

For communicating on railroads between towers and moving trains. This will be of immense service where unnecessary stopping of trains is an item of importance.

AND A THOUSAND OTHER VALUABLE USES

We particularly desire to introduce the Radio Telephone for river work—on the waters of the Mississippi and tributaries, not only for steam boats where it is convenient or a genuine economy for the captain to talk direct to a landing station or another boat long before his arrival or passing, but between small towns and stations on opposite banks between which there is no telephone cable.

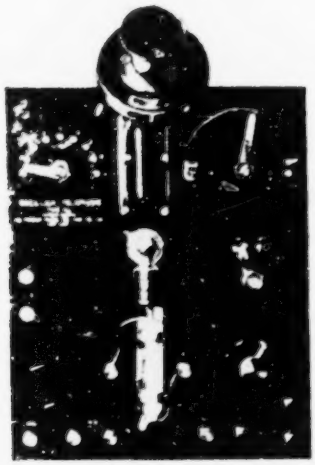
As shown in the accompanying cuts the new type of De Forest Radio Telephone is distinctly different from all other types in every particular, from principle to detail, it marks a great advance.

Simplicity of operation and greatest possible freedom from adjustment have been carefully sought, and the present model can be easily manipulated by any intelligent person who follows the very few instructions which are needed.

The arc used in previous types has been completely eliminated. The generator of the high frequency currents is a modification of the now famous De Forest Audion which has been in use for years in the best commercial wireless stations. The Bulletin of the United States Bureau of Standards shows that the Audion is fully 50 per cent more sensitive than any other known form of detector. Its use has doubled the receiving range of wireless equipment during the past few years. It is employed almost to the exclusion of other detectors by the U. S. Navy. The Audion is the one device, above all other factors, which made possible telephony from Coast to Coast on the Bell Telephone System.

It is entirely fitting, therefore, that a form of this famous device should have been developed into a generator of high frequency currents for telephoning without wires, for its constancy and thorough reliability are its distinguishing features and these are absolutely essential in a practical commercial wireless telephone.

RADIO TELEPHONE
Type OJ



The cut illustrates the smallest size of transmitter. All the instruments are mounted on a panel of Formica measuring 11 by 18 inches, including the oscillion Bulb or Tube, potentiometer for close regulation, filament rheostat, impedance coils, loading inductance, telephone transformer coil, microphone transmitter, fixed condenser and minor accessories. With the set a battery delivering 150 to 300 volts is required. This may be composed of flashlight cells, or a motor generator is supplied where the set is to be used a great deal. The filament operates from a small storage battery. A variable condenser in oil is needed also and is connected to binding posts V C

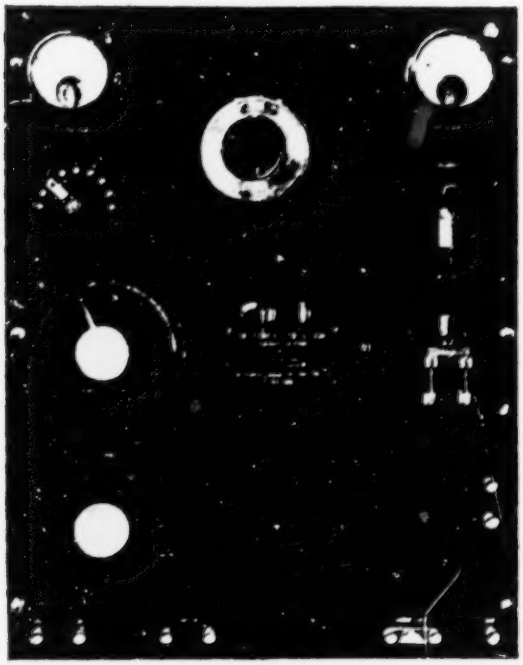
This type of set is particularly adapted for yacht use to communicate to club houses, other ships and residences; also for any purpose where a radius of from one to five miles is sufficient. It may be used as a wireless telegraph transmitter of continuous waves as well, having two or three times the telephone range.

The life of the Oscillion Bulb or Tube when properly used is from 300 to 500 operating hours, equivalent to about a year's service. The set is extremely simple. Once adjusted, no attention is required other than to keep the batteries charged.

This type of radio telephone is furnished as a transmitter only or complete with receiving cabinet and all accessories, as desired. It occupies small space, is simple to install, can be operated by almost any one and is thoroughly reliable and efficient.

RADIO TELEPHONE

Type OB1



The cut illustrates the standard radio telephone transmitting panel, measuring 18 by 24 inches. Upon it are mounted all the various parts, all of which, except the transmitter arm, the loading inductance switch, the variable condenser knob, and meters are mounted on the rear. This protects the parts and simplifies the operation.

On the rear are placed the large Oscillion Bulb or Tube, the cooling fan for same, loading coil, telephone transformer and variable condenser, impedance coils and minor accessories.

The two ammeters on the front of the panel operate at highest efficiency, the one showing the filament current and the other the radiation. By this the operator actually sees himself talk, for the speech causes corresponding deflections of the pointer, showing at all times the condition of the set at a glance.

With the set a motor generator is furnished, designed to operate on any available electric circuit. This furnishes 1,200 volts direct current to the Oscillion.

This small type of set has successfully transmitted speech over a distance of 100 miles, in connection with an antenna 300 ft. high. With a lower antenna, the range would, of course, be less. The set is recommended that it may be employed also as a wireless telegraph transmitter of continuous waves. Its range when so used is from two to three times the telephone range, where the Ultraudion Detector is employed at the distant station.

With this transmitter it is only necessary to connect the antenna and ground to the proper binding posts, connect to the 110 volt direct current source and to the generator and the set is ready to operate. When 110 volts direct current is not available a second generator is provided, directly connected to the motor of the motor generator, to supply same.

For telegraphing where a crystal detector or a plain audion detector is used at the distant station, we supply a chopper or whistling circuit, at additional cost, so that the signals may be received. But it is always recommended, on account of the greatly increased range, to transmit undamped or continuous waves and equip the distant station with the Ultraudion Detector or Receiving Cabinet.

When this transmitter is adjusted to the desired wave length no further change is required, it being merely necessary to throw the transfer switch from talking to listening or vice versa.

The set is furnished as a complete transmitter, ready to install, or as a complete sending and receiving station, as desired.

RADIO TELEPHONE

Type OB2.

This is a larger panel than the Type OB1 Radio Telephone transmitter and is equipped with two Oscillion Bulbs or Tubes having a cooling fin common to both. The output is approximately 250 watts into an antenna of 10 ampères. The motor generator is also of larger capacity, delivering 1,500 volts to the Oscillion Tubes.

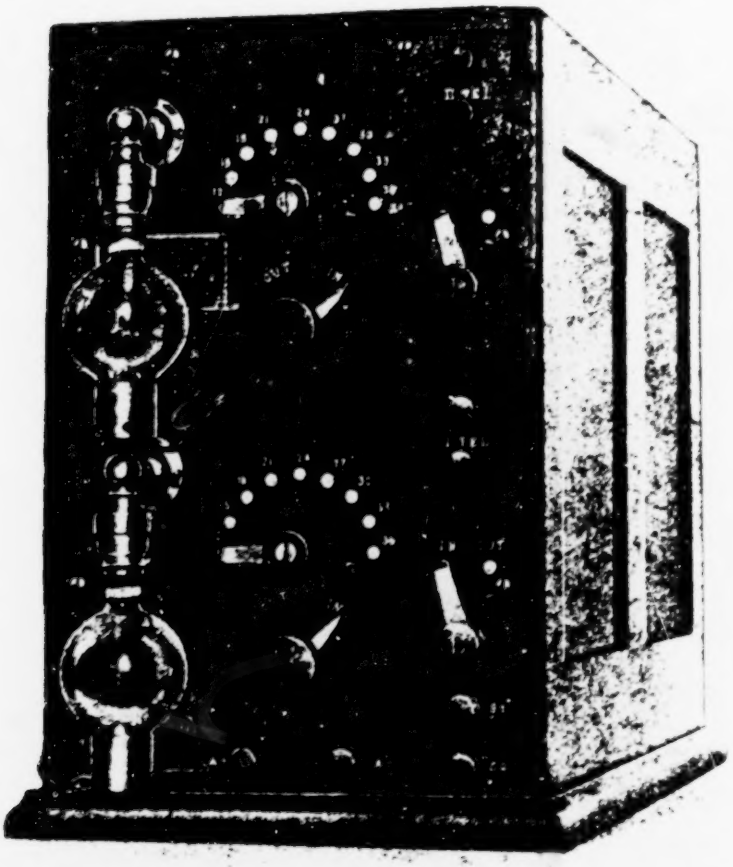
With a suitable antenna the telephone range is from 150 to 200 miles over water and the telegraph range about twice to three times this where the Ultraudion Detector is employed at the distant station.

It may be used either as a telephone or a telegraph, and where a crystal detector is employed at the distant station the transmitter is equipped with a chopper or whistling circuit as in the Type OB1 Transmitter.

With each set of every type complete instructions are furnished.

Prices are quoted on receipt of specifications as to range desired, character of service whether public or private, character of land between stations and kind of power available. If possible a rough sketch should be sent, showing altitudes and general contours to enable us to quote intelligently.

AUDION AMPLIFIER



Type P 2, Two-Step Amplifier.

The De Forest Audion Amplifier in connection with the fies the sound of the received voice, or signals, from 5 to 1, the type supplied.

This device increases signals of small intensity with absolute fidelity, and without lag or distortion and is thoroughly reliable. It is the one device, which above all other makes possible telephone communication between the Atlantic and Pacific coasts on the lines of the Bell system. (The A. T. & T. Co. is licensed under the DeForest Audion Patents for wire telephone work.)

Where a greater volume is desired than the Radio Telephone Sets provide, or where the distance between stations is greater than the range of the Set alone, the Amplifier will enable the desired results to be obtained.

This instrument is made in several styles with various degrees of amplification and is more fully described in our special bulletin covering same.

N. B.—This Company owns all the wireless telephone patents of Dr. Lee de Forest and John Stone Stone, covering every method of loose coupling, tuning, microphone-in-earth-connection, audion and audion amplifier, etc., etc. We own or are licensed under 185 U. S. Letters patent. Infringers of our telephone system patents will be prosecuted.

UNITED STATES PATENT OFFICE.

REGINALD A. FESSENDEN, OF ALLEGHENY, PENNSYLVANIA.

WIRELESS TELEGRAPHY.

SPECIFICATION forming part of Letters Patent No. 706,735, dated August 12, 1902.

Application filed December 15, 1898. Serial No. 740,419. (No model.)

To all whom it may concern:

Be it known that I, REGINALD A. FESSENDEN, a citizen of the United States, residing at Allegheny, in the county of Allegheny and State of Pennsylvania, have invented or discovered certain new and useful Improvements in Wireless Telegraphy, of which improvements the following is a specification.

The invention described herein relates to certain improvements in the electrical transmission of signals from one station to another without the use of conductors connecting such stations.

In the methods heretofore employed the electromagnetic waves generated at the receiving-station produce voltages in the receiving-circuit. These voltages passing through a suitable material normally non-conductive render the same conductive, and thereby permit the passage of a current through a circuit in which said material, usually termed a "coherer," is included. After the cessation of the voltages produced by each series of electromagnetic waves generated at the sending-station the coherer must be operated on in some way to restore it to normal or non-conductive condition.

The object of the present invention is to provide for the generation by currents produced by electromagnetic waves of currents in a second element or circuit and by the reaction of the current in this second element or circuit on the field formed or produced by the currents in the receiving-wire to produce motion which is directly or indirectly observable.

In general terms the invention consists in the generation by electromagnetic waves of a current directly or indirectly in coils at the receiving-station, the current in said coils inducing a current in another element or circuit which is arranged in such relation to the coils that the current induced therein reacts with the field produced by the coils, thereby producing motion.

The invention is hereinafter more fully described and claimed.

In the accompanying drawings, forming a part of this specification, Figure 1 is a diagrammatic view showing the arrangements employed at the sending and receiving stations. Figs. 2 and 3 are diagrammatic views illustrating modifications of the receiving apparatus. Fig. 4 is a side elevation of the apparatus shown in Fig. 3, and Fig. 5 is a further modification of the receiving apparatus.

The apparatus employed at the sending-station may be similar to that now in use for the generation of electromagnetic waves and consists of an induction-coil 1, having its primary coil in circuit with a generator 2, said circuit having a make-and-break mechanism 3 included therein. One of the discharging knobs or terminals 4 is connected with the vertical sending-conductor 5, while the other knob or terminal is grounded. I have found that by placing a capacity formed by a body 5ª of conducting material having a comparatively large radiating-surface the waves generated at the sending-station have a very much higher energy, thereby correspondingly increasing the effect or energy of the current produced in the receiving-conductor.

The terms "sending-conductor" and "receiving-conductor" are employed herein as indicating all of the circuits at the sending and receiving stations from top to ground, if grounded, or if not grounded from one extreme end to the other extreme end, including all apparatus in series with the circuits, while the term "radiating portion" indicates all of the sending-conductor from top or extreme end of same to point of junction with the apparatus for effecting the oscillatory charging and discharging thereof, such as sparking terminals, transformer-coils, armature-windings, &c. By the term "electromagnetic waves" as used herein is meant waves of a wave length long in comparison with the wave length of what are commonly called "heat waves" or "radiant heat." By "grounded conductor" is meant a conductor grounded either directly through a capacity, an inductance, or a resistance, so that the currents in the conductor flow from the conductor to ground, and vice versa, when electromagnetic waves are being generated. The terms "tuned" and "resonant" are used herein as one including the other. By the term "current-operated wave-responsive device" as used herein and by me generally is meant wave-responsive devices having their contacts good contacts and operated by currents produced by electromag-

2621

netic waves. They are hence to be distinguished from wave-responsive devices depending for operation upon varying contact resistance.

At the receiving station the receiving conductor is formed by a wire or wires 6, projecting up vertically or at an inclination to a suitable height, which are also grounded. A coil or coils 7 are arranged in the circuit of the receiving conductor 6, and an element or coil of wire 8, forming a closed circuit, is supported with a freedom of movement in such relation to the coil or coils 7 that the current produced by the electromagnetic waves will induce a current in the element 8. The element 8 is supported, preferably, in such manner that a plane at right angles to its axis will form an angle of approximately forty-five degrees (45°) with a plane at right angles to the axis of the coils 7, so that the reaction of the current induced in said element with the field produced by the coils 7 will cause the element 8 to move with reference to the coils 7. This motion of the element may be observable by means of a mirror 9, attached thereto, reflecting a beam of light on a scale, or said element may form a part of the circuit of a recording-siphon, &c.

As shown in Fig. 2, the coils 7 may be connected to the secondary coil 11 of a transformer whose primary coil 12 is connected in series with the receiving-wire.

A desirable means for transforming the electromagnetic waves into recordable motion is shown in Figs. 3 and 4. The element 8 is balanced on supporting-rods or knife-edges 13, one of which is formed of a good electrical conductor, as silver, the element 8 being preferably formed by a silver ring. A carbon block 14 is so arranged that a portion of the ring between the supporting-rods will normally rest lightly thereon. This microphonic contact, the conducting pivotal support, and the portion of the ring between them form parts of an electric circuit, which also includes a generator 15 and a recording instrument 16 as a telegraphic sounder or the receiver of a telephone. When a current is generated, as above described, in the coil 7, the element or ring 8 will be caused to press on the carbon block, thereby increasing its conductivity. When using a telephone-receiver as a recording instrument, the generator 15 is preferably of a character capable of producing an alternating current, as such current causes a constant vibration of the diaphragm, the vibrations increasing in intensity with an increased flow of current in the circuit. This increase in intensity of action with increased flow of current is characteristic of this form of receiver and also of the form shown in Fig. 1. In this it is sharply differentiated from such devices as the coherer, which either give a strong indication or do not give any. This characteristic is advantageous in that if the signal sent—any dot—be too weak to give an action of the full intensity it may still in most cases be read and not missed entirely, which is of value in sending code-messages.

In the construction shown in Fig. 5 the circuit of the generator is divided, one branch including a coil 16 and connected to a microphonic contact 14, while the other branch of the circuit includes a reversely-wound coil 16' and is connected to a microphonic contact 14'. These contacts are arranged on opposite sides of the ring 8 and are so adjusted that the ring will normally rest equal on both blocks, so that an equal current will flow through both of the coils 16 16', thereby maintaining a magnetic bar 17, suspended between the coils in equilibrium with relation to the coils. Adjustable resistances may be placed in the circuits of the coils, thereby avoiding the necessity of delicate adjustments of the carbon blocks. When the coils and the ring or element 8 are energized, the pressure of the latter on one contact is increased and that on the other decreased, thereby correspondingly changing the resistances in the two branches. The increased flow of current through one coil and decreased flow through the other coil, due to the change in resistances, will produce a greater movement of the magnetic bar 17 than if only a single coil were used. The movement of the bar 17 can be rendered observable in many ways known in the electric signaling art—as, for example, by securing a mirror thereon.

As shown in Fig. 1, a condenser 19 may be connected in shunt with the field coil or coils 7 for the purpose of obtaining as large a current as possible in the field-coil 7, as this increase in current will give a greater torque to the ring 8. When no condenser is employed, this large current must flow in the vertical wire, and there would be great loss of energy on account of the resistance of wire 6, and, further, without the condenser a large amount of energy will be required to give the statical charge to the receiving-conductor. Hence on account of the small energy furnished by the wave a large current cannot be obtained in field coil or coils 7 without the condenser. By employing a condenser of the proper size current in wire 6 may be made to have a value equal to the difference between the current in the field coil or coils and the current in the condenser. Either of these currents may therefore be large and either or both may be used to produce motion, while the current in wire 6 may be kept so small that there is practically no loss of energy on account of its resistance or of the statical charging of the receiver, and all the energy may be used in producing motion. Without the condenser the current in the field coil or coils 7 will be practically a quarter phase behind the voltage on account of the self-inductive lag in the field-coil. If the condenser were substituted for the field coil, there would be a current in it nearly a quarter-phase in advance of the voltage due to the capacity lead. When both the

95

field coil and the condenser are introduced one in shunt with the other, there will be a current in the field coil or coils lagging ninety degrees (90°) and in the condenser a current leading ninety degrees (90°). The sum of two currents one hundred and eighty degrees apart in phase is equal to the difference between their values. Hence if there is a current in the field coil or coils of one ampere and in the condenser a current of nine-tenths (9/10) of an ampere the current in the receiving-wire will be one-tenth (1/10) of an ampere.

By the employment of a condenser in shunt with the coil or coils 7 the current in the receiving wire is reduced without reducing the current in the coil or coils 7, so that the resistance-drop, which is at times sufficiently great to affect the operation of the system, is eliminated or so reduced as not to have any material effect.

It is preferred to place a shunt circuit containing a condenser across the terminals of the induction-coil at the sending-station for the purpose of maintaining sustained radiation. This shunt-circuit must be tuned to the receiving-conductor; otherwise the oscillations produced by it will have no action upon the wave-responsive device at the receiving-station. This shunt-circuit by virtue of its capacity stores up an additional amount of energy, and when a spark passes across the gap, since the sending-conductor can radiate energy at a given rate, it must continue to radiate for a longer time in order to dissipate this additional stored-up energy.

I am aware that apparatus consisting of a fixed primary and a movable secondary circuit has been used for detecting oscillatory currents. This apparatus was a modified form of an earlier alternating voltmeter, a silver disk or thick-rimmed annulus being substituted for the wire coil used in the voltmeter and delicately suspended so as to have a long period of swing. This apparatus was used not for the purpose of detecting electromagnetic waves emitted and received by unclosed circuits, but for detecting the magnetic inductive effects which one closed circuit (having rapidly-oscillating currents produced in it by a transformer, Hertz oscillator, or other suitable means) produced on another closed circuit. The effects to be obtained by such an apparatus were therefore different in kind from those sought in wireless telegraphy and the method of producing them were different from that described herein. This Northrup apparatus was used to detect magnetic-induction effects to a distance of approximately one hundred yards. Although distances somewhat longer could doubtless have been attained with such apparatus, the method employed by Northrup is not available for commercial wireless signaling, as magnetic-induction effects fall off as the cube of the distance, and approximately ten thousands of millions times the energy would be required to obtain effects with the Northrup apparatus at a distance of one hundred miles.

The construction of Northrup's receiving instrument is not suitable for the purposes of wireless telegraphy, as the movable member consists of a disk or thick-rimmed annulus, whereas the movable member of the receiving-mechanism for wireless telegraphy should be a ring formed of thin wire (indicated at 8 in the drawings) having a ratio of internal and external diameters equal or approximately equal to unity. If a disk or thick-rimmed annulus should be used as the movable member of the receiving-mechanism for wireless telegraphy, the efficiency of such mechanism would be so greatly reduced as to render it inoperative, for the reason that the currents induced in the disk or thick-rimmed annulus tend to get as near as possible to the center of such parts, and thereby weaken the reactive effect between the fixed and movable parts and to exert small torque, and, further, as the disk and thick-rimmed annulus have low self-induction the currents induced in them tend to get out of phase with the currents in the fixed coil or coils, and hence the torque is weakened. Moreover, the period of oscillation of a disk or thick-rimmed annulus for a given restoring force is so long that extremely-powerful restoring forces must be used to enable a mechanism having such a movable member to record signals at commercially-practical speeds, and since the force varies as the square of the speed deflecting forces many thousands of times greater must be employed than is required in the receiving-mechanism described herein. In other words, the thin light ring 8 will work with but a fraction of the energy required to operate a disk or thick-rimmed annulus. By the employment of a thin ring of good conducting material and a fixed coil of few turns, as shown in the drawings, the electrical forces between fixed and movable members of the receiving-mechanism are rendered more efficient, and hence the force necessary for commercially-practical signaling is greatly lessened.

The inapplicability of the Northrup apparatus is further shown by the fact that the coils of the fixed member of his apparatus consist of a large number of turns of wire, so that the resistance in such coils is high, whereas a commercially-practicable instrument for wireless telegraphy should have its fixed coil or coils formed by a few turns of wire, and consequently of low resistance. By the employment in the receiving-instrument of a fixed coil or coils of few turns and a movable member formed by a thin light ring of highly-conducting wire high resonance effects combined with a rapid natural period of the moving part and a maximum efficiency are attained and the advantageous use of transformers, as in Fig. [illegible] is rendered possible.

2623

It is characteristic of the method shown that the receiving mechanisms are actuated by currents produced by electromagnetic waves and not by voltages, as in the case of the coherer. Hence when the receiving mechanisms described herein are used in connection with a secondary circuit said circuit is controlled by the currents generated by electromagnetic waves and not by voltages. It is also characteristic that when a secondary circuit is used in connection with the type of wave-responsive device shown in Figs. 3, 4, and 5 a portion of the secondary circuit is traversed and controlled by currents produced by electromagnetic waves. It is further characteristic of my improved system that the indications produced by the receiving mechanism herein described are dependent upon the total amount of energy emitted to form the signal and are not, as in the case of the coherer, dependent upon the maximum of the voltage.

I claim herein as my invention—

1. As an improvement in the art of transmitting signals electrically by electromagnetic waves, the method herein described, which consists in the generation of electromagnetic waves at one station and transforming the energy of the currents generated by such waves at the receiving-station into the energy of motion, that is without the necessary interposition of a secondary or auxiliary generator for the production of such motion, substantially as set forth.

2. As an improvement in the art of transmitting signals between stations by electromagnetic waves, the method herein described which consists in causing the radiation of electromagnetic waves from a grounded conductor, generating voltages by such waves in a conductor at the receiving-station and transforming the energy of each of said voltages into the energy of motion, substantially as set forth.

3. As an improvement in the art of transmitting signals electrically between stations by electromagnetic waves, the method herein described which consists in producing an electromagnetic field in a receiving mechanism consisting of relatively fixed and movable members arranged in operative relation to each other by the generation of electromagnetic waves at the sending-station, thereby causing a movement of one of the parts of the receiving mechanism, substantially as set forth.

4. As an improvement in the art of transmitting signals electrically between stations by electromagnetic waves, the method herein described which consists in the generation of a current or currents in a portion of a receiving mechanism consisting of relatively fixed and movable members by the generation of electromagnetic waves at the sending-station and then producing a current or currents in the other portion of the receiving mechanism by the current or currents generated by the electromagnetic waves, whereby one part of the receiving mechanism is caused to move relative to the other part, substantially as set forth.

5. As an improvement in the art of transmitting electrical energy by electromagnetic waves the method herein described, which consists in maintaining a secondary circuit in an energized condition and controlling the energy of said circuit by current effects produced by electromagnetic waves flowing through a current-operated wave responsive device forming a portion of the secondary circuit.

6. As an improvement in the art of transmitting electrical energy by electromagnetic waves the method herein described, which consists in prolonging the oscillations of an energy-radiating conductor by energy from a source external to the radiating conductor and tuned to the period of the radiating-conductor, substantially as set forth.

7. As an improvement in the art of transmitting electrical energy by electromagnetic waves the method herein described, which consists in the generation of electromagnetic waves at one station and transforming the energy of the currents generated by such waves at the receiving-station into the energy of motion, varying the motion thus produced by varying the amount of energy delivered at the receiving-station without the necessary interposition of a secondary or auxiliary generator for the purpose of such motion, substantially as set forth.

8. As an improvement in the art of signaling by electromagnetic waves the method herein described, which consists in generating electromagnetic waves in a grounded conductor at the sending-station, receiving such waves at the receiving-station and transforming the energy of electromagnetic waves so received into the energy of motion by means of a receiving instrument having a low resistance, substantially as set forth.

9. As an improvement in the art of transmitting electrical energy, the method herein described, which consists in varying the conductivity of a secondary circuit at the receiving-station by motion produced by currents generated by electromagnetic waves, substantially as set forth.

10. As an improvement in the art of transmitting electrical energy, the method herein described, which consists in the generation of electromagnetic waves at one station, transforming the energy of the currents generated by such waves at the receiving-station into energy of motion, varying the currents in two or more local circuits by such energy of motion and transforming the energy of such currents into the energy of motion, substantially as set forth.

11. As an improvement in the art of transmitting electrical energy, the method hereby described, which consists in generating electromagnetic waves at one station, transforming the energy of currents generated by such

waves into the energy of motion, varying the currents in two or more local or secondary circuits by such energy of motion, transforming the energy of the varied currents into the energy of motion and causing the energies of motion so produced to operate in the same direction, substantially as set forth.

In testimony whereof I have hereunto set my hand.

UNITED STATES PATENT OFFICE.

HARRY SHOEMAKER, OF PHILADELPHIA, PENNSYLVANIA, ASSIGNOR TO CONSOLIDATED WIRELESS TELEGRAPH AND TELEPHONE COMPANY AND MARIE V. GEHRING, OF PHILADELPHIA, PENNSYLVANIA.

ART OF TRANSMITTING INTELLIGENCE.

SPECIFICATION forming part of Letters Patent No. 711,131, dated October 14, 1902.

Application filed August 9, 1902. Serial No. 119,030. (No model.)

To all whom it may concern.

Be it known that I, HARRY SHOEMAKER, a citizen of the United States, residing at Philadelphia, in the county of Philadelphia and State of Pennsylvania, have invented a new and useful Art of Transmitting Intelligence, of which the following is a specification.

My invention relates to an improvement in the art of signaling electrically, more particularly by means of electroradiant energy which is impressed upon the natural media and which causes manifestations at the receiving-stations.

My invention comprises a method of receiving signals represented by electroradiant energy by causing such energy to change the resistance of a material in virtue of a magnetic field caused by such energy. Of such materials many are well known in the electrical arts, though bismuth is a good example of the same.

My invention consists of a method of rendering intelligible transmitted electroradiant energy by causing such energy at the receiving-station to cause a varying magnetic field in which is placed a material having the property of changing its resistance under the influence of magnetism and producing a signal or recording a message by the changes of resistance of such material.

My invention consists, further, of a method of rendering intelligible transmitted electroradiant energy by causing such energy in the receiving-circuits to vary, either directly or indirectly, the resistance of a material which is not in the nature of an imperfect electrical contact, but rather in the nature of a continuous conductor of relatively low resistance or great conductivity as compared with the imperfect electrical contacts known in the art of wireless signaling.

By the use of bismuth or other materials which change their resistance when in a magnetic field I am enabled to construct a receiving device for wireless signaling systems in which the received electroradiant energy causes, directly or indirectly, a change in the resistance of such material, and the change of such resistance is caused to control a local circuit to produce a signal or record a message. The use of such material is distinctly different from the use of imperfect contacts now well known in the art as coherers and the like, which in general manifest great and sudden changes in resistance and are more or less uncertain in their action.

By employing bismuth or other similar material and subjecting it to the varying magnetic field due to received electroradiant energy there is attained a smooth variation in the resistance of a circuit, which renders the receiver certain in its operation, in marked contrast with the operation of the imperfect electrical contacts heretofore employed in wireless signaling systems.

Besides bismuth it is to be understood other materials may be used which have the same property—namely, that of changing resistances when in a magnetic field. I have found that iron, and even copper, behaves similarly to the bismuth when placed in a magnetic field.

Reference is to be had to the accompanying drawings, in which—

Figure 1 is a diagrammatic view of the receiving-circuits of a wireless signaling system in which a bismuth conductor is placed in the field generated by received energy within a winding in series with the aerial conductor. Fig. 2 is a diagrammatic view in which the bismuth or like material is connected in series with the aerial conductor. Fig. 3 is a diagrammatic view in which a loop of bismuth or like material is used for the aerial conductor and comprises in these two aerial conductors bismuth or other material which are connected at their tops. Fig. 4 is a modified arrangement of the circuits of a receiving device in which by proper proportions of the electrical constants of the circuit the magnetic field produced by the arriving energy is very great compared with the amount of such energy. Fig. 5 is similar to Fig. 4, except that the bismuth or other material is placed in the field generated by a winding through which an abnormal amount of current flows under the influence of a certain amount of received energy.

2627

In Fig. 1, A represents the usual aerial conductor, in series with which is connected the winding B', which connects at its lower terminal with earth plate E. The received radiant energy causes oscillations in the aerial conductor and through the winding B' to manifest a magnetic field. Within this field is placed a length of bismuth, preferably in the form of wire B, forming a part of the circuit including the telephone-receiver T and the source of energy *b*. The bismuth is normally has a certain resistance, and there is accordingly a certain current flowing through the telephone-receiver T, producing no sound. Upon the reception of electrical energy, however, the resistance of B varies, due to the magnetic field generated by the winding B', and there results a fluctuation of current through the receiver T, causing a sound to be produced in accordance with the received energy. In this manner the code characters or other signal characters may be read by the ear.

In Fig. 2, A is the usual aerial conductor, in series with which there is connected a bismuth winding B, which connects at its lower terminal with the earth plate E. The received radiant energy causes oscillations through said conductor B, producing a magnetic field. This magnetic field generated by the winding B' causes in the conductor B a change of resistance, which is noted by means of the telephone-receiver T and the source of energy *b*, as in the case of Fig. 1.

In Fig. 3, A A represent two aerial conductors, of bismuth or similar material, which conductors are joined at their upper ends. The left-hand conductor A connects directly to earth plate E, while the right-hand conductor connects to earth plate E through condenser C. The condenser C is so large as to be perfectly transparent to the oscillations received in the right-hand conductor A, and in effect, therefore, the right-hand conductor A is connected directly to earth. In shunt to the condenser C, or, what is the same thing, in series with the two conductors A A are connected the telephone-receiver T and the source of energy *b*. In this case the conductors upon the reception of radiant energy are surrounded by a magnetic field, and such field in turn causes a variation of resistance of such conductors A A. There results, therefore, a variation in the resistance of the circuit embracing source of energy *b*, telephone-receiver T, right-hand conductor A, and left-hand conductor A. From such change of resistance there results a variation in the flow of current through the telephone-receiver T, producing a signal, as previously described.

In Fig. 4, A is the usual aerial conductor, between which and the earth plate E are connected the condenser C and inductance-winding B in parallel relation to each other. The condenser C and this inductance-winding B are so related to each other as to their magnitudes that they form what is known as an "antiresonant" or "closed-resonant" circuit for the frequency of oscillations which are received upon the aerial conductor A. When the radiant energy received upon the said conductor A is of a particular frequency, there is set up in the local circuit, embracing the condenser C and the inductance B in series with each other, a current many times greater than that appearing in the aerial conductor itself. This inductance B is composed of bismuth wire. The excessive current flowing through it, due to the relations above stated, causes an abnormally powerful magnetic field to be produced in the vicinity of said winding, resulting in a correspondingly great variation in resistance of the bismuth wire forming the winding of such inductance. The variation in resistance of such bismuth inductance B is recorded then by the telephone-receiver T, with the aid of the source of energy *b*, as described in the previous cases.

In Fig. 5, A is the aerial conductor, between which and the earth plate E are connected in parallel with each other the condenser C and the primary winding B'. The relations of this condenser C and the winding B' are the same as described in connection with Fig. 4 for the condenser C and the inductance B. As described in connection with Fig. 4, the winding P will produce an abnormally strong magnetic field due to the antiresonant effect, and within this field is located a bismuth conductor B, as in the case shown in Fig. 1, and the variation of resistance of such conductor is recorded by the telephone-receiver T with the aid of the source of energy *b*.

I do not wish to be limited to the precise arrangement of circuits as herein described by me, for it is apparent that this system may be applied in many other relations by those skilled in the art. It is broadly new to me to generate a magnetic field by the received electroradiant energy and to cause such field to vary the resistance of certain materials and cause such variation of resistance to control a local circuit to produce a signal or record a message.

It is of course to be understood that in place of telephone-receivers sensitive relays may be employed to control local circuits. Furthermore, the telephone-receivers may be omitted and the primary of a transformer substituted therefor, and in the secondary circuit of such transformer may be placed telephone-receivers or other devices, such as relays and the like. By this arrangement upon a change of resistance in the bismuth or like material there is a large change in the strength of the current in the primary of the transformer, because a large source of energy is used, resulting in a great change in the ampere-turns of the primary of the transformer, and consequently a great change in the potential of the secondary circuit.

In the arrangement shown in the drawings the telephone-receivers are to be of low resistance, so that normally there may be a relatively large current flowing through the

2628

telephone-receiver. In virtue of this slight change in resistance of the material there will be considerable change in the current strength, and therefore considerable change in the ampere-turns in the telephone-receiver.

The bismuth or other material as used in my system may be in the form of a wire. The cross-section of the conductor or wire is such as to permit the use of a considerable current in the circuit of the wave-responsive device, which is, in fact, the wire. Heretofore in wireless signaling systems but very slight amounts of current had been used in the wave-responsive device. In the case of coherers and the like the current has been extremely small, and in the case of other systems employing a metallic conductor as a wave-responsive device the current employed has been extremely small. In my system, however, I am enabled for the first time in the art to employ currents of relatively great magnitude through the wave-responsive device. This is an advantage which is appreciated in view of the considerations named above. In other words, if the telephone-receiver T were of high resistance as compared with the bismuth or like material the slight fluctuation in the resistance of such material would cause but slight effect in the receiver. The bismuth or other material being of relatively low resistance, the telephone-receiver should also be of relatively low resistance.

What I claim is—

1. The method of rendering intelligible transmitted electroradiant energy representing a signal, which consists in varying the resistance of a material by a magnetic field which varies with the transmitted energy, and recording the variations of resistance of said material.

2. The method of rendering intelligible transmitted electroradiant energy representing a signal, which consists in changing the resistance of a material by a magnetic field due to the transmitted energy, and recording the changes of resistance of said material.

3. The method of rendering intelligible transmitted electroradiant energy representing a signal, which consists in changing the resistance of a material by a magnetic force due to the transmitted energy, and producing a signal by the change of resistance of said material.

4. The method of rendering intelligible transmitted electroradiant energy representing messages, which consists in transforming the received electroradiant energy into the energy of electric currents, generating a magnetic field by said currents, subjecting a material to said field to vary its resistance, and recording the resistance changes of said material.

5. The method of rendering intelligible transmitted electroradiant energy representing messages, which consists in transforming the received electroradiant energy into the energy of electric currents, producing a magnetic force by said currents, changing the resistance of a material by said magnetic force, and recording the resistance changes of said material.

6. The method of rendering intelligible transmitted electroradiant energy representing a message, which consists in generating a magnetic field by the received energy, changing the resistance of a material by said magnetic field, and recording the resistance changes of said material by varying the current strength in a circuit of a translating device.

7. The method of transmitting intelligence, which consists in impressing upon the natural media electroradiant energy representing a message, converting the received energy into the energy of electric currents at the receiver, increasing the current component of said energy of electric currents in a closed resonant circuit, generating a magnetic force by the increased current component, varying the resistance of a material by and in accordance with said magnetic force, and recording the resistance changes of said material.

8. The method of rendering intelligible electroradiant energy transmitted through the natural media and representing a signal, which consists in producing a magnetic field by the received energy, changing the resistance of a material by the influence of said magnetic field, and producing a signal by the change of resistance of said material.

9. The method of rendering intelligible electroradiant energy transmitted through the natural media and representing a signal, which consists in producing a magnetic field by the received energy, changing the resistance of a mass of bismuth by the influence of said magnetic field, and producing a signal by the change of resistance of said mass of bismuth.

10. The method of rendering intelligible transmitted electroradiant energy representing a signal, which consists in varying the resistance of a mass of bismuth by a magnetic field which varies with the transmitted energy, and recording the variations of resistance of said mass of bismuth.

11. The method of rendering intelligible transmitted electroradiant energy representing a signal, which consists in generating a magnetic field by the received energy, varying the resistance of a material by said varying magnetic field, and recording the resistance changes of said material.

12. The method of rendering intelligible transmitted electroradiant energy representing a signal, which consists in generating a magnetic force by the received energy, varying the resistance of a mass of bismuth by said magnetic force, and recording the resistance changes of said mass of bismuth.

UNITED STATES PATENT OFFICE.

LEE DE FOREST, OF NEW HAVEN, CONNECTICUT, ASSIGNOR TO THE GREATER NEW YORK SECURITY COMPANY, OF NEW YORK, N. Y., A CORPORATION OF NEW YORK.

SPACE TELEGRAPHY.

SPECIFICATION forming part of Letters Patent No. 730,246, dated June 9, 1903.

Application filed March 8, 1902. Serial No. 97,239. (No model.)

To all whom it may concern:

Be it known that I, LEE DE FOREST, a citizen of the United States, and a resident of New Haven, in the county of New Haven, State of Connecticut, have invented a new and useful Improvement in Space Telegraphy, of which the following is a full, clear, and exact description.

My invention relates to improvements in those systems of electric signaling between two points which use natural media for the transmission of the electrical impulses and which are ordinarily referred to as "space" or "wireless" telegraphy.

My invention comprises certain novel features, which will be herein described, and particularly pointed out in the claims.

In the drawings accompanying herewith I have shown and in the specification have described numerous forms of apparatus in illustration of the manner of applying my invention to use and of adapting it to different circumstances and requirements. I am aware, however, that it may be embodied in other forms, and do not, therefore, wish to be understood as limiting myself to the forms herein shown, but seek to claim my invention in any form in which it may be embodied. The scope of my invention is to be determined by a reference to the accompanying description and particularly to the claims attached thereto.

The accompanying specification is a description of my invention as embodied in the figures of drawings given.

Figure 1 shows an apparatus employing my invention used as a sender. Fig. 2 shows diagrammatically a simple form of apparatus containing my invention employed as a receiver. Figs. 3 to 7, inclusive, show modified forms, which by the use of either a responder or an energizing device may be used either as a sender or as a receiver. Figs. 8 to 11, inclusive, show my invention in various modifications employed as senders. Figs. 12 to 23, inclusive, show forms of my invention employed as receivers. Figs. 24, 25, and 26 show other arrangements of parts employed in my invention.

While I have shown and described some arrangements employed as receivers and others as senders, and while some of the arrangements shown are better adapted for the one use than for the other, there is in general nothing to forbid the employment of any of the arrangements shown in either capacity by substituting either a responder or an energizing apparatus for whichever of these is shown.

In systems of space or wireless telegraphy now being employed a failure to attain the efficiency or power desired is largely due to the fact that the electrical waves emanating from the sending device are rapidly damped or decreased in intensity or amplitude. In other words, while the maximum intensity or amplitude of the waves may be satisfactory their persistence is unsatisfactory, as they rapidly fall in amplitude to nothing. In consequence of this their energizing action upon the receiving-antenna being repeated but a few times does not have the cumulative energizing effect that a much weaker impulse would have if repeated a greater number of times. The effect is comparable to the effect produced upon a vibrant body, as a piano wire, by its note being sounded loudly for a very short time or less loudly for a much longer time.

I have discovered a means whereby I am able to produce with each signal a longer and better sustained series of waves, the same means also lending themselves readily to use in the receiver, in which use they have special and marked advantages.

It is a well-known fact that if two adjacent and parallel wires of equal length are connected each with a terminal of any form of apparatus producing electrical oscillations of high frequency the charges in said wires at any point of their length are of exactly equal intensity and of opposite phase. The currents flowing in these two wires are also at corresponding points equal in amount and flow in opposite directions. If these wires are the equivalent of one-quarter or any multiple thereof of the wave length of the electrical oscillations transmitted thereto, very efficient reflection occurs at the ends of these wires, with the result that stationary or standing waves are set up, caused by the incident and reflected oscillations. The system then divides up into quarter or half wave lengths

2635

with nodes and loops symmetrically situated on each wire. At the nodes of these electrostatic stationary waves a conducting-body, as a wire bridge, may be placed across both wires without seriously interfering with the action beyond. At a distance of one-quarter wave length from said nodes loops are formed, at which points the maximum possible difference of potential between the two parallel wires exist. Such a system of parallel conductors is known in the art as the "Lecher" system of wires. The phenomena involved in this system have been worked out theoretically, notably by Lord Rayleigh, Drude, Heaviside, and others, and have been set forth by these and other people, as in the following instances: By E. Lecher, in *Wiedemann's Annalen*, No. 41, page 850; Barton and Bryan, *Phil. Mag.*, August, 1897; E. Marx, in *Wiedemann's Annalen*, No. 11, 1898; Lord Rayleigh, *Phil. Mag.*, No. 43, 1897; E. Lecher, *Wiedemann's Annalen*, No. 42; Heaviside, *London Electrician*, April 9, 1897; Bjerknes, *Wiedemann's Annalen*, No. 55, page 121. As has been pointed out by investigators, what is known as the "wire and sheath" return, consisting of a wire surrounded by a coaxial tubular conductor insulated therefrom, is only a special form of the Lecher system and is subject to the same laws as the simple system. The general theory has shown that in this [illegible] system of conductors, or for a wire with return, the self induction and capacity are evenly distributed and are reciprocals per unit length of the system—that is to say, the capacity and self induction cancel each other as far as the dimensions of the wire are concerned, that the period of vibration is independent of the distance between the two wires and of their diameters. Such a system of conductors is known in the art as a "distortionless" circuit. The velocity of propagation thereon for high-frequency oscillations is approximately that of light. For example, this is the velocity when the resistance per unit length is negligible compared to the self induction and when this self-induction is the reciprocal of the capacity per unit length. These conditions are satisfied when the wires are less than one-half millimeter in diameter and less than two meters long.

The formula for the self induction per unit length of the Lecher system is $L = \text{Log nat } \frac{d}{r}$, where d is the distance between the centers of the two parallel wires and r their common radius. The expression for the capacity per unit length is the reciprocal of the above, or $= \frac{1}{\text{Log nat } \frac{d}{r}}$, hence the remarkable property of the Lecher system that the velocity of the propagation of an electric wave along its length is not dependent in the least on the size of the wires or of the distance between their centers, and this velocity comes out as equal to the velocity of light. This being the case it will be at once understood how the period of any section of a Lecher system embraced between two consecutive bridges is a function of the length between said bridges alone. Hence in arrangements shown in Figs. 20, 21, 22, and 24 the velocity of propagation along section B B is identical with that along section B^2 B^2, and if the length of these two sections is the same the period of oscillation of each section will be the same, but although the product (L S) be the same for both, L is small in B B and large in B^2 B^2, while S is large in B B and small in B^2 B^2. Now the relative quantities of electromagnetic and electrostatic energies depend wholly on the ratio of L to S. Where self-induction is large and capacity small, we will have a greater proportion of the total energy as energy of inertia or momentum. Where capacity is large and self induction small, we will have a greater proportion of the total energy as energy of elasticity. Hence in passing from B B to the section B^2 B^2 we will have a transference of energy from the electrostatic to electromagnetic—for example, two opposite charges are traversing B and B. When these pass upon B^2 and B^2, respectively, where the capacity is less their potential difference must be increased, and vice versa.

On account of losses from resistance, leakage, and imperfect reflection at bridges or open ends in such a system of parallel wires as is here described the stationary waves set up therein are never perfect, and therefore absolute nodes are never found in practice, although with suitable reflecting devices the approximation thereto when a slowly-damped wave train is transmitted is very good. We get instead points of maximum and minimum potential difference and of current, whose magnitudes are dependent on the coefficient of resistance, leakage, and reflection.

Ordinarily the order of magnitude of the energy involved in the two sets of waves (the electrostatic and electromagnetic) is the same, and if the parallel wires were infinitely small in diameter the magnetic force must equal the electric, and the greater the surface the less becomes the magnetic force relative to the electric, the one increasing as the other decreases.

The characteristics and advantages of the Lecher system are:

(a) It is to a high degree a resonant vibrator—that is, it has a very marked period of its own and is very little responsive to oscillations of any other frequency than its own.

(b) It is a poor radiator and consequently a persistent vibrator, persisting for some time in its vibrations since they are set up, therefore producing a long wave-train and damping slowly. This is because most of the lines of force lie in the space between the two conductors and the radiation losses are therefore small, except when a radiator is attached.

One authority states that the observable magnetic effect from a Lecher system, even strongly excited, does not extend beyond three centimeters from the parallel wires.

(c) By reason of the stationary waves set up higher potentials are obtained than are otherwise possible.

(d) The nodes and loops of these stationary waves are fixedly located, thus enabling connections to be made with the wires at any phase of the wave desired.

(e) The system may be easily and accurately tuned to any frequency desired.

(f) It is simple in its mathematical and theoretical aspects. Its constants are easily calculated and regulated, so that the dimensions of a system for securing definite results may be readily predetermined. This has not yet been satisfactorily done for other forms of apparatus employed in connection with currents of very high frequency, such as are employed for space signaling. The velocity of transmission in a simple Lecher system is approximately equal to that of light. Therefore the wave lengths or frequency may be readily determined and exactly defined. A brief description of the phenomena and laws obtaining in such a system of parallel conductors has been given by me in the *American Journal of Science* for July, 1899.

I have discovered that these characteristic features of the Lecher system of wires render them especially adaptable for use in wireless telegraphy. In their application they are flexible, being adaptable to various modifications as may be required by the various circumstances, as the type of transmitter or receiver employed and the practicable dimensions of the apparatus, as the height and character of the upright wire.

In the figures of the drawings accompanying herewith I have shown various modifications in which the Lecher wires are employed, some representing the sending apparatus and others the receiving apparatus, although in general either a sending or a receiving apparatus may be employed with either.

In Fig. 2 I have shown Lecher wires B B in use with a receiver, one wire, B, connected with an upright wire or antenna A and the other, B', connected with the ground G or other capacity. The equivalent length of the upright wire or collector A is one-quarter of the wave length of the natural oscillation to which the system is attuned. At a distance of one-half wave length from the foot of the upright, as at 1, occurs the first node, and if the wires are long enough other nodes are formed separated by the same distance as the node 2 shown in the figure. At these nodes the wires may be connected by no-resistance bridges, as C C, without destroying or seriously affecting the oscillations or the propagation of the waves. These bridges may also be grounded, as shown by dotted lines at G' in Fig. 4 without affecting the period of vibration.

If the wires be continued one-quarter wave length beyond the last node, as shown in Fig. 2, a loop of electrostatic force will be formed by the open-end reflection. At such open ends all the energy of the system is electrostatic. Therefore, as the sensitive device operated by a difference of potential across its terminals, such as a coherer or other responder, may be inserted most advantageously at a static loop, these ends form a desirable location for such a device. The dotted lines D, Figs. 2 and 3, indicate the position and intensity of such waves in the system. In Fig. 2 a responder is shown at R as inserted between the open ends of the Lecher wires. Such a device may, however, be inserted wherever an electrostatic loop occurs. A sensitive device operated by current or electromagnetic stationary wave, such as a bolometer or thermo element, should be placed at the loop of an electromagnetic wave. The electromagnetic waves do not coincide in location with the electrostatic waves, but, as is well known in the art, are separated along the wire by ninety degrees or by a quarter-wave length. The relative positions of these different waves are shown in Fig. 3, in which the dotted line D represents the electrostatic wave, and D' the electromagnetic wave. A bolometer or other device operated by current or electromagnetic waves may be located at any loop of an electromagnetic wave. Such a device is shown at R in Fig. 3.

Since the simple antenna A is a strongly-damped vibrator and the system of parallel wires attached at its base a weakly-damped or strongly-resonant vibrator, it sometimes results that a violent oscillation received by the antenna, if strongly damped, may excite in the parallel conductors vibrations having the distinctive period of said conductors, regardless of the period of the exciting impulse. Were this exciting impulse, however, a long wave-train, interferences in the parallel wires would arise and the effect above described could not obtain. Conversely, if this long wave-train have the frequency to which the wire system is attuned this latter would be violently excited. Thus by regulating the sensitiveness of the receiving device R response to oscillations other than those to which the system is attuned may be prevented.

In Fig. 4 the wire and sheath return is shown, wherein, as in the Lecher wires, the self-induction and capacity are also evenly distributed. This, as shown, consists of a central conductor, as a wire B, and an outer tubular conductor B surrounding it. These two conductors may be connected at the location of electrostatic nodes by bridges, as C. As shown in Fig. 4, the waves travel upon the outer surface of the inner conductor and back on the inner surface of the tubular or outer conductor. The connections, however, of the antenna and the ground may be reversed, or we may regard the annular space between the two conductors as the region within which the

other oscillations are suffined. A responder, reflector, or other equivalent device is shown as located at R, the same being at an electrostatic loop.

In Fig. 3 the wires B and B are simple Lecher wires, such as described in connection with Fig. 2. The antenna A of Fig. 2 is however replaced by the conductive cylinder A connected with wire B and the central wire A' which latter is connected with the wire B. These form a wire and sheath return system employed as a radiating or a receiving antenna. This is only an exemplification of the wire and sheath return employed as an antenna. When used as a radiating antenna [illegible] the inner conductor A' and the field of force is limited part [illegible] between the exterior of conductor A and the ground and the greater portion concentrated in the annular space between the cylinders A and A'. This arrangement results in a conservation of force only a small portion of the energy being radiated out into space at each oscillation, but the oscillations are continued for a considerable time. When used as a receiver the wire system of the type of the responder should be located at a static loop as shown at R.

In Fig. 4 the conductors B B are the simple Lecher conductors, one of them being connected with the ground G. The simple antenna is replaced by two plates A' and A' which may be considered as the extension of the Lecher conductors. If the plates of the plates at parallel and adjacent, the greater part of the energy is concentrated in the field between them. The receiving in front of A will at one instant be occupied by lines of force representing a positive wave, and that in front of A' will at the same instant be occupied by lines of force representing a negative wave. The respective lines of force radiating from these plates are constantly changing their direction, extending from one to another in a series of opposite sign in the same amount of wave length distant from the respective plates. In the region of the plates parallel with the plates the [illegible] equal radiations from both plates will neutralize each other, while in the region [illegible] affected by the ground plate as A' [illegible] the plate A' tends to [illegible] preventing [illegible] the intensity [illegible] lines of force [illegible] plate and the earth [illegible] between this plate and the earth [illegible] the reflection set [illegible] For these reasons radiation [illegible] comparatively slight. The [illegible] direct propagation is therefore [illegible] A' and the plate A' tends to [illegible] which proceed in the approximate direction the direction [illegible] set propagation is perpendicular to its plane. This feature enables the direction of propagation of the effective energizing or signaling waves to be in a measure controlled or directed or. In other words, provides for the maintenance of a neutral zone or zones. If these plates be mounted so as to be rotatable upon a common axis the position of these neutral zones may be controlled, and the same apparatus may thus be utilized for signaling in any direction desired, while approximately non-effective in other directions. This fact may also be utilized in preventing interference between different apparatus located in a common field of energy which would otherwise interfere with each other. When used as a receiving antenna, the rotative plates may be utilized for receiving messages coming from a given direction, while in considerable measure neutralizing or cutting out the waves coming from other directions. It follows that if the device has a direction of maximum propagation and directions of minimum or no propagation it will conversely have directions of maximum and minimum sensitiveness to the reception of waves, from which it follows that if more than one series of waves are coming in it will be most responsive to those which come from its direction of maximum efficiency, and also by turning the plates to the position where the message is most clearly received the plate A' will be found to be facing the direction from which the impulses are received. In this way the direction from which a signal comes may be approximately told.

If it is desired that both antenna be charged alike instead of oppositely, as may at times be desirable to secure increased radiating or collecting power, this result may be obtained by inserting between the base of one and the leg of the Lecher system connected thereto a retarding device, such as a coil or length of wire equivalent in length to one-half wave length of the oscillation for which the system is attuned. Such a coil is shown at E in Fig. .

If used as a receiver, a wave traveling down the antenna A' will be delayed by its passage through the coil E by a time equal to one half its period, and so will enter upon the arm of the Lecher wires at a time when a wave of opposite sign enters upon the other arm of the Lecher system. Thus the necessary condition of waves of opposite sign in the Lecher system is fulfilled.

In Figs. 8, 10 and 11 means are shown for exciting my apparatus or for transmitting thereto the electrical oscillations necessary when employed as a sender. These figures do not show all the means which may be employed for this purpose, but are given as illustrative of well-known means which adapt themselves to this use.

In Fig. 8 a "static" method of charging is shown. The parallel or Lecher wires are shown as of only one half wave length. In series in the bridge across their ends is a

denser K. In shunt around this condenser are a spark-gap S and the secondary coil T of a transformer T T. When this condenser is charged to the breaking-down point of the spark-gap S, a discharge occurs at this point, and this serves as a connecting-bridge between the parallel wires, and these wires are set in vibration as a Lecher system. Part of the energy is reflected back at O and O', forming stationary waves with nodes at O and O'. A part goes into the upright conductor or antenna A and is radiated outward.

In Figs. 9, 10, and 11 the Lecher system is charged inductively—that is, the secondary T of the transformer is in the circuit of the Lecher system and oscillates therewith, while in Fig. 8 it is not in such circuit and does not enter directly into its oscillations. In fact, in Fig. 8 the transformer may be replaced by any source of electrical energy giving the requisite potential.

In Fig. 9 the parallel wires are shown as equal to one-quarter wave-length and the coil T, forming the secondary of the transformer, is equivalent to one-half wave-length. The primary coil T' of this transformer is connected in series with the condenser K and spark-gap S. This primary circuit is charged from any suitable source of energy I. It is obvious that for self-connection of the primary coil T and the capacities K be so chosen that the natural period of oscillation of this primary system shall be that of the adjoining Lecher system.

Fig. 10 shows a system essentially the same as in Fig. 8, except that a condenser K is connected to the Lecher wires at the static loop. A condenser so located is the equivalent of a certain length of [illegible] wire, so that a system containing a condenser adjusted with a period of oscillation longer than one corresponding to the length of wire necessary for a system of a given period. The effective capacity of such a condenser depends somewhat upon its location in the Lecher system, being most effective when placed at a point where the potential difference across its terminals is a maximum.

It has been observed that a capacity-bridge [illegible] located across the two Lecher conductors exerts a greater or less disturbing or retarding effect upon the wave-system according as it is located near an electrostatic loop or near a node. If near a loop, the potential difference across its terminals is greater. Hence the quantity of electricity capable of being stored thereby is correspondingly greater, and the effect of the retarding up at such a point is proportional, therefore, to the location of the condenser in the Lecher system. In other words, while the absolute capacity is independent of this location, its effective or equivalent capacity is dependent thereon.

The use of a condenser as a means for adjusting the period or equivalent length of a system, for which purpose it is most effectively placed adjacent a static loop, should be distinguished from its use in a bridge to prevent direct connection between the wires, as is shown at K in Figs. 1, 17, and 25, where it is located at a static node. In this position it acts as a bridge, while at the same time insuring the transfer to the system beyond the bridge of a larger percentage of the energy than would a plain wire bridge or direct connection. It is, however, not altogether devoid of an effect in lengthening the period of the system. Condensers may be employed for both of these purposes in the same system, as is shown in Figs. 1 and 25.

Fig. 11 shows the Lecher wires cut at static loop and a condenser inserted in such run between the Lecher wires and the secondary terminals of the transformer. Here also the armatures of the condenser behave as the equivalent of a certain length of wire, this relation depending upon the amount of surface in the condensers and the distance between the armatures. This affords a ready means of attuning the system by changing the distance between the armatures of the condensers, since the maximum potential of opposite sign occurs at the terminals of the secondary T of the transformer, the middle point of the coil must be one of zero potential and may therefore be grounded as shown at G without interrupting the action of the system.

In the devices shown in Figs. 10 or 11 are used as receivers the transformer coils T and T' should be reversed in arrangement, as shown in Fig. 12, the low-potential coil T being connected with the Lecher wires and the secondary T' in circuit or responder R may be substituted for the spark-gap S. The same necessity arises in this case as in the sender for tuning alike the two circuits shown.

In the receiver it is not always necessary to ground any point of the Lecher system of wires. In Fig. 13 if a node be formed, as at O, at the base of the upright A stationary waves will be set up in the parallel wires as before, and in the absence of any earth-connection the energy of the oscillations has no opportunity to leak away and must be consumed only in heat and reflection-losses in the receiver-instruments. To insure the formation of a node at O, a key, capacity, or the like, may be connected at this point. If a condenser as K be connected at O between the two wires, its capacity should be small. A condenser at this point in the system shown acts as a bridge.

In Fig. 14 is shown a method of reducing the actual length of wires required to form the equivalent of the proper wave-length, which consists in inserting coils L L in the wires of the Lecher system. The several coils should be inserted at loops of current where the inductive effect will be maximum. If the Lecher wires are to be bridged, these bridges should connect the middle points of two corresponding coils, as shown at C.

32061

In Fig. 1 I have shown a system which employs both inductance-coils L and a condenser K as lag producing or period adjusting devices. I also show a condenser K employed as a bridge at the base of the antenna. The bridge C, which connects the two inductance-coils, might be of the same form. The wave-producing device is of the same construction and is connected with the system in the same manner as that shown in Figs. 9 and 10.

The use of bridges at the nodes of wires of more than one half wave length and placing the receiving instrument beyond said bridge or bridges has one advantage. The bridge, if grounded, will have the effect of leading off or grounding waves of such length that their nodes are formed elsewhere and will thus screen or protect the responder or equivalent receiver from the effect of all waves except those which are of the length for which the apparatus is adjusted. Upon waves of the proper length the bridges produce but little effect of this character.

It is not always necessary that the two parallel or Lecher wires be of the same length. Fig. 15 shows an arrangement in which the responder R is located at a static loop of the wires and one quarter wave length removed from the base of the upright wire. At this point in the lower wire we have a static loop formed by open end reflection. The node at O may be connected to earth or to a capacity K'.

In all the foregoing figures the upper end of the upright wire has been considered as the location of the static loop, of which the node was at the base one-quarter wave length below it. If a body having a large capacity, as K' in Fig. 16, be located at the top of the upright wire or antenna, its capacity may be such as to produce reflection in the waves oscillating in the upright conductor equivalent in sign to the reflection obtained at a bridge in the Lecher wire system. This means that a static node will be formed at this point with a loop at the lower end. The earth connection then should be at a point along the parallel wires one quarter wave length distant from the base of the upright wire or antenna where the second node will be located. As the capacity K' makes a static node at the top of the antenna where ordinarily is a static loop, the location of the condenser K corresponds with a static loop. The condenser K of Fig. 10 is also at a static loop. In both cases the condenser represents or absorbs a certain amount of the wave length and is so located as to shorten the apparent wave length of the Lecher system. The condenser K in Fig. 1 shortens the length necessary in B B, and consequently also shortens the length necessary in A to still keep A in resonance with the attach of Lecher system. The responder may be located, as shown, in shunt around the condenser.

In Fig. 17 is shown a convenient form of using the Lecher wires. Here the two wires which are insulated, are twisted together, forming a twisted pair, the distance between them being regulated by the thickness of the insulation. It is desirable that the pitch of the twist be not too steep. The twisted pair is well adapted to use upon a spool or coiled in any other manner which may be desirable to economize space or to secure portability. If the two simple parallel wires untwisted were coiled upon a spool, with convolutions parallel and near together, interference by induction between adjacent convolutions would arise; but when closely twisted such adjacent convolutions of the coil if not too close together will not interfere with one another. In any considerable length of the convolution one wire will first be adjacent to another carrying current of like sign and then to one carrying current of opposite sign, so that for any considerable length of wire the inductive effects from the two wires in the convolutions adjoining will be neutralized. In practice I have successfully used such wires twisted with a pitch equal to three turns to the inch wound upon a spool about three inches in diameter with successive turns separated about an eighth of an inch. Their use is not, however, limited even a near approximation to the above proportions, which are given only to show what has been found successful without any intention of limiting myself thereto.

So far as I am aware such a method of embodying the Lecher wires and of utilizing their advantages has never before been used. It retains practically all the theoretical advantages of the straight parallel wires embodied in a compact form, which makes the apparatus portable and practical. Wherever in the accompanying drawings or description straight Lecher wires are shown or described, it is to be understood that the twisted pair, as above described, may be substituted, either coiled, as shown in Fig. 18, or disposed in any suitable way—for instance, as in Fig. 19. Bridges, a condenser, or any other device such as described in connection with the previous features may be inserted as desired and are controlled in location and action by the same principles as apply to the simple straight wires. In Fig. 17 a responder R, choke coils M M, a battery N, and a telephone Q, or other indicating instrument are inserted in a local circuit after the manner common in wireless telegraph apparatus.

As shown in Fig. 17, the responder is placed across the open end of a loop and one-quarter wave length distant from the responder, and one-half wave length distant from the upright A is or may be placed a bridge C. To avoid shunting the local circuit about the responder, which would occur if a no-resistance bridge or a metallic connection were used, a condenser K is placed in the bridge, which condenser is of sufficient capacity to act as a no-resistance bridge for the Hertzian oscillation, while for

2640

30682

113

ing an effective interruption for the local current.

When employed in the sending device, it may be desirable for purposes of insulation to immerse the entire system in oil.

In Figs. 20, 21, and 22 are shown constructions by which the potential may be simply and effectively transformed either to raise or lower it, as desired. The principle therein illustrated may be employed either in the sender or the receiver, but is more especially recommended for use in the receiver.

The general theory shows that the mutual induction of the Lecher wires decreases as the two parallel wires are brought closer together, becoming zero for the wires in actual contact, and that conversely the capacity of the system is thus increased. Consequently if one system of such parallel wires, as B B, Fig. 20, of length equivalent to one-half wave length of the vibration transmitted be added to another system, as B^2 B^2, of the same period of electrical vibration, but having its two parallel wires farther apart, then this second system B^2 B^2 may take up the impulse transmitted from the first system unaffected as to its period of vibration, yet transformed to a wave of higher potential, but of correspondingly diminished magnetic energy or current. On the same principle if the first-mentioned system—say of one-half wave length—have for the dielectric between its two parallel wires a substance of higher specific inductive capacity than that between the two parallel wires of the second system then the capacity of the first system per unit length is greater than that of the second system. The electrical energy will therefore be transferred from the first to the second system altered in its relative proportions of electrostatic and electromagnetic energies. So in the arrangement last described the transformation will be, as before, to step up the potential and to diminish the currents flowing in the second system. Such a system is illustrated in Fig. 21, in which the wires B B are parallel throughout their length, but the first half wave length from the upright is inclosed in a casing H, containing oil. Thus I employ one pair of parallel wires—for example, of length equivalent to a half wave length of the vibration transmitted—immersed in and separated by an oil, and connected to one end of this system another system of parallel wires of a length also equivalent to one-half wave length, but normally separated by air or other dielectric of small specific inductive capacity, and thus obtain between the two wires of this second system a higher difference of potential than existed between the wires of the first system. Such immersion in a fluid may result in a change in the wave length required for a given period. In Fig. 22 a combination of both plans is shown, the first half wave length B B being immersed in oil and also having its wires closer together than the second half wave length B^2 B^2, which are separated only by air.

When desirable to still further increase the self-induction of one of such systems of parallel wires as I have described, I may insert at corresponding points in each of the two wires inductive or momentum coils of suitable impedance and construction, as shown at I. I, Fig. 24. Similarly, to increase the capacity of the other system I may attach to each of the parallel wires thereof an armature of a condenser of suitable area, as shown at i i, Fig. 24.

Such combination of systems as I have here described thus affords a step-up or step-down device entirely differing from "transformer coils," ordinarily so called, a device novel and useful in its application to the art of space telegraphy.

In all the figures so far mentioned the antenna is shown as directly connected with what may be called the "resonant" conductors—that is, with the parallel conductors which produce the stationary waves. This is, however, not a necessity, as the resonant conductors and the antenna may contain device in circuit therewith whereby the wave effect is transmitted inductively. Such a construction is shown in Figs. 25 and 26, in which I I represent the two coils of a transformer or induction-coil, one being in the circuit of the resonant conductors B B and the other in the circuit of the antenna. When applied to a receiving device, the coil I is the primary coil and I' the secondary. When applied to a sending device they would be reversed in position or function. This method of connecting the parallel conductors and the antenna may be employed in the forms illustrated in the other figures. As shown in these figures, the conductors extending each way from the center of the coil T to the first bridge C or the point where the first node is formed are each the equivalent of a half wave length, the condensers K, if employed being taken into consideration. The condenser may, however, be dispensed with and its effect produced by employing some other form of lag-producing device, such as the impedance-coils, after the manner illustrated in Fig. 14 or the conductors B B lengthened to the proper amount. The indirect or inductive method of connecting the antenna with the parallel Lecher conductors B B is employed generally with the arrangements in the other figures of [illegible] shown therein. Where one or the description or claims one form of connection is specified, I am to be understood as stating or claiming the other form to be an equivalent [illegible].

In Fig. 25 the last system with which the receiver circuit is connected is inductively connected with the other systems after the manner shown in Fig. 12.

In Figs. 25 and 26 condensers h h are

2641

shown as placed in and forming part of the conductive systems after the manner shown in Figs. 11 and 12.

In Fig. 26 the antenna is directly connected with the ground G and inductively with the resonant system by the coils T T', and described in connection with Fig. 23.

In the foregoing description I have endeavored to describe such modifications and variations in the apparatus which may be employed as will make clear the principles of my invention without intending to show all the modifications which are available or feasible. Other combinations will suggest themselves to one familiar to the art.

I am not to be understood as limiting myself to the forms or exact combinations of various elements shown, as I am aware of other modifications and combinations which might be employed. The further multiplication of the drawings seems, however, to be unnecessary, as those given serve to clearly set forth the principles of my invention.

The scope of my invention is to be determined by reference to the claims terminating this specification, in which the omission in any claim of any element or the failure to include therein any qualification of an element is to be understood as a distinct statement that such element or qualification is not essential to that particular combination.

Having thus fully described my invention, I claim as new and desire to secure by Letters Patent—

1. In an apparatus for space telegraphy, in combination, an antenna and two parallel conductors adapted to act inductively upon each other, one of which is electrically connected with the antenna, said conductors being each equivalent to a multiple of a quarter-wave length.

2. In an apparatus for space telegraphy, in combination, an antenna and a plurality of parallel conductors cooperating therewith and adapted to develop stationary electrical waves.

3. In an apparatus for space telegraphy, the combination with an antenna of two conductors each equivalent in length to a multiple of a quarter-wave length and adapted to the production in each other of stationary electrical waves.

4. In space telegraphy, in combination, parallel conductors adapted to the production of stationary electrical waves, and an antenna connected to one of the conductors whose natural period of vibration corresponds to that of the parallel conductors.

5. In space telegraphy, in combination, parallel conductors adapted to the production in each other of stationary electrical waves, and an antenna connected at a node of said waves to one of the conductors and having a natural period of vibration corresponding to that of the parallel conductors.

6. In space telegraphy, in combination, plural conductors adapted for the production of stationary electrical waves, bridges connecting said conductors at points corresponding with the nodes of said waves and an antenna connected with one of the conductors.

7. In space telegraphy, in combination, plural conductors adapted for the production of stationary electrical waves, bridges connecting said conductors at points corresponding with the nodes of said waves, ground connections for said bridges and an antenna connected with one of the conductors.

8. In space telegraphy, in combination, a plurality of mutually-inductive conductors adapted for the production of stationary electrical waves, an antenna connected to one of said conductors and a receiver located at a loop of said stationary waves.

9. In space telegraphy, in combination, a plurality of mutually-inductive conductors adapted for the production of stationary electrical waves, an antenna connected to one of said conductors at a node of said waves, and a receiver located at a loop of said waves.

10. In wireless telegraphy, the combination with an antenna, of two conductors of substantially uniform separation, one of said conductors being connected with the antenna.

11. In wireless telegraphy, the combination with an antenna of two conductors of substantially uniform separation, one of said conductors being connected with the antenna, and tuning or period adjusting devices connected with said conductors.

12. In space telegraphy, in combination, an antenna, two conductors adapted to the production of stationary waves, one of said conductors being connected with the base of the antenna and a condenser between the base of the antenna and the other of said conductors.

13. In space telegraphy, in combination, an antenna, two parallel conductors connected at one end and having a condenser between their other or open ends, and an antenna connected with the open end of one conductor.

14. In space telegraphy, in combination an antenna, two parallel conductors connected at one end and open at the other, and an antenna connected to the open end of one conductor, the joint lengths of said conductors being equivalent to a multiple of one-quarter of the wave length for which the antenna is adapted.

15. In space telegraphy, in combination, an antenna, a conductor consisting of a wire and sheath return having one end of the sheath connected with the antenna, and the corresponding end of the wire connected with a capacity.

16. In space telegraphy, in combination, an antenna, a conductor consisting of a wire and sheath return having an end of one of said members connected with the antenna.

17. In space telegraphy, in combination, an antenna, a conductor consisting of a wire and sheath return having one end of one of said

members connected with the antenna, said wire and sheath return being equivalent in length to a multiple of a quarter wave length.

18. In space telegraphy, in combination, an antenna, a conductor consisting of a wire and sheath return connected with a capacity, said wire and sheath return being equivalent in length to a multiple of a quarter-wave length.

19. In space telegraphy, the combination with parallel conductors forming a resonant system, an antenna connected with one end of said system, and means connected with the said conductors for the production therein of stationary electrical waves, of a capacity connection between said conductors adapted to lengthen their period of vibration.

20. In space telegraphy, the combination with parallel conductors forming a resonant system, an antenna connected with one end of said system, and means connected with the said conductors for the production therein of stationary electrical waves, of a capacity connection thereto adapted to lengthen their period of vibration.

21. In space telegraphy, the combination with parallel conductors forming a resonant system, an antenna connected with one end of said system, and means connected with the said conductors for the production therein of stationary electrical waves, of a capacity connection between said conductors adjacent to a static loop of said waves.

22. In space telegraphy, the combination with an antenna and two parallel conductors adapted to form a resonant system, one of which conductors is connected with the antenna, of condensers inserted between said parallel conductors.

23. In space telegraphy, the combination with an antenna and two parallel conductors adapted to form a resonant system, one of which conductors is connected with the antenna, of condensers inserted between said parallel conductors at points corresponding substantially with the loops of the electrostatic waves therein.

24. In space telegraphy, the combination with an antenna and two parallel conductors adapted to form a resonant system, one of which conductors is connected with the antenna, of lag-producing devices connected with said parallel conductors.

25. In space telegraphy, the combination with an antenna and two parallel conductors adapted to form a resonant system, one of which conductors is connected with the antenna, of lag-producing devices connected with said parallel conductors, and means for adjusting said devices to control the amount of lag produced thereby.

26. In space telegraphy, the combination with an antenna and two parallel conductors adapted to form a resonant system, one of which conductors is connected with the antenna, of condensers connected with said conductors and having their poles adjustable toward and from each other.

27. In space telegraphy, in combination an antenna, parallel conductors connected therewith and adapted to the production of stationary waves, and a condenser between the ends of said conductors.

28. In space telegraphy, in combination, an antenna, a conductor connected therewith and adapted to the production of stationary waves, a condenser between the ends of said conductor and a wave-indicating device connected in shunt about said condenser.

29. In an apparatus for space telegraphy, in combination, an antenna and two parallel and mutually-inductive conductors, one of which is electrically connected with the antenna and a wave-indicating device between said conductors.

30. In an apparatus for space telegraphy, in combination, an antenna, two parallel and mutually-inductive conductors one of which is electrically connected with the antenna, said conductors being each equivalent to a multiple of a quarter-wave length, and a wave-indicating device connecting said conductors at a point equivalent to a multiple of a quarter-wave length distant from said antenna.

31. In an apparatus for space telegraphy, in combination, an antenna, a plurality of parallel conductors coöperating therewith to develop stationary electrical waves, and a wave-indicating device placed in the field of said waves substantially at a loop thereof.

32. In an apparatus for space telegraphy, the combination with an antenna, and two parallel conductors each equivalent in length to a multiple of a quarter-wave length and adapted to the production of stationary electrical waves, and a wave-indicating device connecting said conductors at a point corresponding substantially with loops of said waves.

33. In space telegraphy, in combination, a plurality of conductors adapted for the production of stationary electrical waves, bridges connecting said conductors and located substantially at nodes of said waves, an antenna connected with one of the conductors and a wave-indicating device connected with said conductors substantially at a loop of said waves.

34. In space telegraphy, in combination, a plurality of conductors adapted for the production of stationary electrical waves, an antenna connected with one of the conductors, bridges connecting said conductors and located substantially at nodes of said waves, and a wave-indicating device connected with said conductors substantially at a loop of said waves and beyond a bridge from the antenna.

35. In space telegraphy, in combination, an antenna, a conductor consisting of a wire and sheath return having the wire and sheath connected one with the antenna and the other with a capacity and a wave-indicating device connected between the wire and sheath.

36. In space telegraphy, in combination, an antenna, a conductor consisting of a wire and

sheath return, one of which is connected with the antenna and a wave-indicating device connected between the wire and its sheath.

37. In space telegraphy, in combination, an antenna, a conductor consisting of a wire and sheath return, one of which is connected with the antenna and a wave-indicating device connected between the wire and its sheath, at a point corresponding substantially with the loop of the waves in said conductor.

38. In space telegraphy, in combination, an antenna, a conductor consisting of a wire and sheath return, one of which is connected with the antenna, said wire and sheath return being equivalent in length to a multiple of a quarter-wave length, and a wave-indicating device connected between the wire and its sheath.

39. In space telegraphy, the combination with parallel conductors, means connected therewith for the production in said conductors of stationary electric waves, of a capacity connection between said wires adapted to lengthen their period of vibration, and a wave-indicating device connected between said wires.

40. In space telegraphy, the combination with parallel conductors, means connected therewith for the production in said conductors of stationary electrical waves, a capacity connection between said wires adjacent the static loop of the waves in said conductors, and a wave-indicating device connecting said conductors adjacent a static loop of the waves therein.

41. In space telegraphy, the combination with an antenna and two parallel conductors which are connected at one end one with the antenna and the other with the earth or other capacity, and a wave-indicating device connected between said conductors.

42. In space telegraphy, the combination with an antenna and two parallel conductors, one of which is connected with the antenna, of condensers inserted between said parallel wires, and a wave-indicating device in shunt about said condensers.

43. In space telegraphy, the combination with an antenna and two parallel conductors which are connected at one end, one with the antenna and the other with the earth or large capacity, and a wave-indicating device connected between said conductors at a point along the wires substantially corresponding to a loop of the wave with which it is designed to operate.

44. In space telegraphy, the combination with an antenna and two parallel conductors, one of which is connected with the antenna, a lag-producing device operative upon said conductors, and a wave-indicating device connected with such conductors.

45. In space telegraphy, the combination with an antenna and two parallel conductors, one of which is connected with the antenna, of lag-producing devices operative upon said conductors, means for adjusting said devices to control the amount of lag produced thereby, and a wave-indicating device connected with said conductors.

46. In space telegraphy, the combination with an antenna and two parallel conductors, one of which is connected with the antenna, of condensers connected with said conductors and having their poles adjustable toward and from each other, and a wave-indicating device connected with said conductors.

47. In space telegraphy, the combination with an antenna, two parallel conductors, one of which is connected with the antenna, of a condenser connected between said conductors substantially at an electrostatic loop of the waves therein, and a wave-indicating device connected between said conductors substantially at a loop of the electrostatic wave therein.

48. In space telegraphy, an antenna, a conductor connected therewith and adapted to the production of stationary waves harmonizing in period with those of the antenna, a wave-indicating device connected with the conductor, and connections with said conductor between the wave-indicating device and the antenna adapted to remove from the conductor such waves as are not in harmony with its designed period.

49. In a sending apparatus for space telegraphy, the combination with a wave-producing device and an antenna, of a conductor connecting the wave-producing device and the antenna and equivalent in length to a multiple of a quarter-wave length, and a second conductor parallel thereto and acting inductively to produce stationary electrical waves.

50. In a sending apparatus for space telegraphy, the combination with a wave-producing device and an antenna, of parallel conductors connecting the wave-producing device and the antenna and equivalent in length to a multiple of a quarter-wave length, and bridges connecting said parallel conductors substantially at nodes of the waves produced therein.

51. In a sending apparatus for space telegraphy, the combination with a wave-producing device and an antenna, of parallel conductors connecting the wave-producing device and the antenna and equivalent in length to a multiple of a quarter-wave length, bridges connecting said parallel conductors substantially at nodes of the waves produced, and ground connections for said bridges.

52. In space telegraphy, the combination with a wave-producing device and a radiating antenna, of a plurality of conductors connecting the wave-producing device and the antenna and the other acting inductively therewith to produce stationary electrical waves.

53. In space telegraphy, the combination with a wave-producing device and a radiat-

38646

ing antenna, of a plu ality or parallel conductors each equivalent in length to a multiple of a quarter-wave length, said conductors being adapted to the production of stationary vibrations, one of said conductors connecting the wave-producing device and the antenna.

In testimony whereof I have hereunto affixed my signature in the presence of two witnesses.

Operating Features of the Audion

Explanation of its action as an amplifier, as a detector of high-frequency oscillations and as a "valve." By E. H. Armstrong

ALTHOUGH the audion has been in use for several years as an amplifier and a detector of high-frequency oscillations, the explanations advanced to account for its action do not appear to be satisfactory. With the idea of pointing out some features of operation which heretofore do not seem to have been

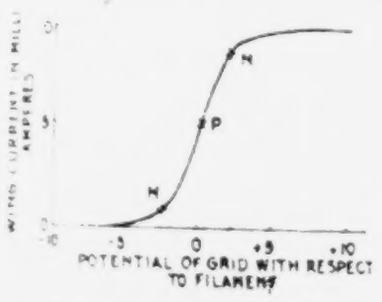

FIG. 1—VARIATION OF WING CURRENT WITH GRID POTENTIAL

with respect to the filament, but only one grid was employed. It was found that, under similar conditions of filament temperature and voltage of the battery B_p, a considerably smaller current was obtained between the filament and plate on the side in which the grid was inserted. In both measurements the grid was left entirely free of any connection with the rest of the apparatus. Obviously the grid obstructed the flow of the thermionic current. Investigation showed that this was due to the charge accumulating on the grid when exposed to bombardment by the electrons passing from

FIG. 4—TIME VARIATION OF GRID POTENTIAL AND WING CURRENT

elucidated the following explanation and oscillograms are given.

The audion is essentially an electron relay, that is, the exhaustion is carried to such a point that the amount of gas present is exceedingly small, and the current between the hot and cold electrodes is entirely thermionic, the absence of gas making impossible the presence of positive ions. The operating characteristic of such a relay is as shown in Fig. 1. This characteristic was obtained in the manner indicated in Fig. 2.

The potential of the grid with respect to the filament was varied in steps between — 10 and + 10 volts, by means of the potentiometer P, corresponding readings of grid voltage and wing current being taken in order to plot the curve of Fig. 1. The characteristic shows that, starting with the grid and filament at zero potential difference, a negative charge imparted to the grid produces a decrease in the wing current and a positive

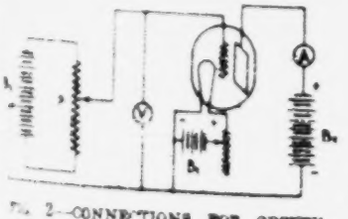

FIG. 2—CONNECTIONS FOR OBSERVING WING CURRENT AND GRID POTENTIAL

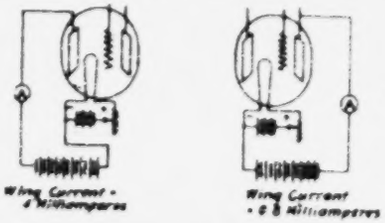

FIG. 3—CONNECTIONS GIVING TWO VALUES OF WING CURRENT

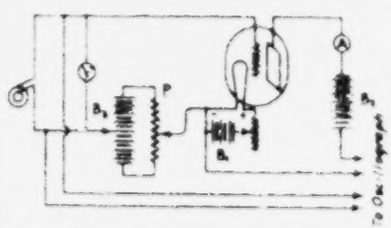

FIG. 5—CONNECTIONS TO OSCILLOGRAPH

charge imparted to the grid produces an increase in the wing current. This is the fundamental action of the audion when used either as an amplifier or a detector. The reason for this action will appear upon examination of the behavior of an audion of the type shown in Fig. 3.

The wings of the audion were placed symmetrically the filament to the wing. The electrons pass readily enough into the grid but cannot easily escape from it and as a consequence of this negative electricity piles up on the grid. The potential assumed by the grid when exposed to this bombardment may be several volts negative with respect to the negative terminal of the filament, it may be the same as the negative terminal or it may be positive with respect to the negative terminal, but it will always be negative with respect to the potential of the field in the plane of the grid which would exist if the grid were removed from the bulb. The negative charge on the grid, therefore, impedes the flow of electrons from filament to plate, causing the decrease in the wing current. The placing of a positive charge on the grid from an external source tends to neutralize the negative charge on the grid, thereby permitting an increase in the wing current. The addition of a negative charge to the grid increases the deflection of the electrons and produces a further decrease in the wing current.

An alternating emf impressed between the grid and the filament causes variations in the wing current in the manner indicated in Fig. 4, the positive alternation producing an increase and the negative alternation a decrease in the wing current. This is the action in-

volved in the audion when it is used as an amplifier.

To substantiate the above and other actions, the writer, working in conjunction with Prof. J. H. Morecroft, of Columbia University, has secured oscillograms which substantiate the idea just presented. Fig. 5

FIG. 6—ACTION OF AUDION AS AN AMPLIFIER

shows the arrangements with which the test was carried out.

The potentiometer P was used to adjust the grid to a potential corresponding to point P at the center of the operating part of the curve shown in Fig. 1. The audion is capable of handling the greatest amount of energy as an amplifier when the grid potential is adjusted to this point.

Fig. 6 shows the oscillogram of the action as an amplifier. The result bears out the explanation already given.

The action of the audion as a detector of high-frequency oscillations is quite different from its action as an amplifier. Since the incoming oscillations are of too high a frequency to affect directly the telephone receiver, the audion must be so connected and adjusted that the cumulative effect of a group of oscillations in the grid circuit is translated into a single low-frequency pulse or variation in the telephone current. This may be done in two ways, one depending on the non-linear form of the operating characteristic of the audion and the other depending on the so-called "valve" action between hot and cold electrodes at low pressures.

Fig. 7 shows the connection used for operating in the first-named manner. The potentiometer P is employed for the purpose of adjusting the potential of the grid to point M on the characteristic curve of Fig. 1. The action is much the same as in one of Professor Fleming's methods of using his valve. A group of high-frequency oscillations impressed on the grid causes corresponding high-frequency variations in the continuous current in the wing circuit, but owing to the fixing of the grid potential at the lower bend in the curve by adjustment of the potentiometer in the grid circuit, the amplitude of the positive part of the high-frequency current in the wing circuit exceeds the amplitude of the negative part. As the positive half-waves are greater than the negative half-waves, more electricity flows in one direction than the other, and the condenser C, through which the high-frequency current in the wing circuit flows, becomes charged, the side connected to the battery B_1 having the positive charge. This charge accumulates in C in a relatively short time, approximately that of the duration of a wave train. C then discharges through the telephones T, the rate of this discharge being determined by the constants of the telephones and the condenser. It is probable that this discharge is aperiodic or nearly so. In any case the main part of the discharge through the telephones is in the same direction as the current due to the battery B_1 and constitutes an increase in the current in the telephones. As this action is repeated for each group of oscillations, a series of wave trains causes what might be regarded (in its action on the telephones) as an alternating current in the telephones superposed on the continuous current and having a fundamental frequency equal to the number of wave trains per second. The action is shown diagrammatically in Fig. 8.

If the potential of the grid is adjusted to the upper bend in the curve of Fig. 1, as at point N, the func-

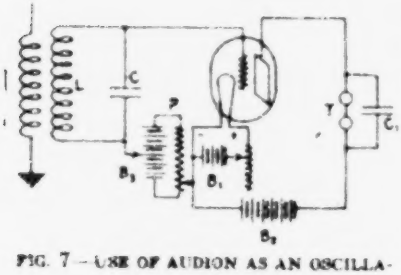

FIG. 7—USE OF AUDION AS AN OSCILLATION DETECTOR

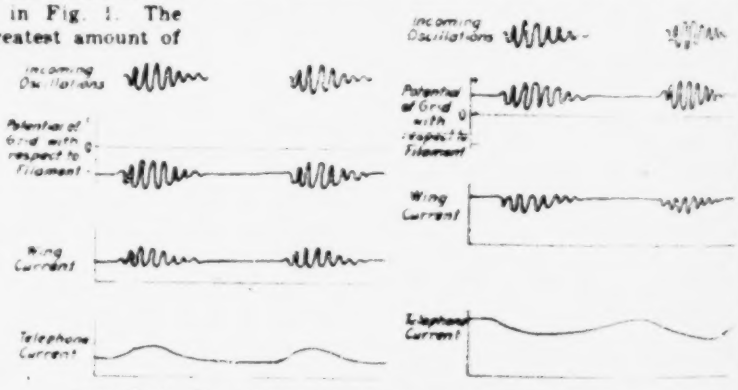

FIGS. 8 AND 9—ACTION OF AUDION AS AN OSCILLATION DETECTOR

mental action will be the same, but the effect of high-frequency oscillations in the grid circuit on the wing current will be reversed. The amplitude of the negative part of the high-frequency oscillations in the wing circuit will exceed the amplitude of the positive part and

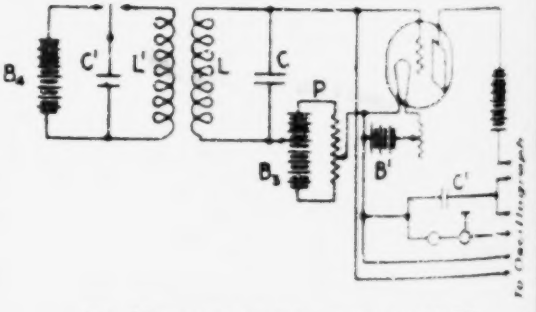

FIG. 10—CONNECTIONS TO OSCILLOGRAPH

the condenser C will become charged, but in the opposite sense, the side connected to the battery B becoming negative. The discharge of the condenser through the telephones will therefore be in the opposite direction to the flow of the continuous current of the wing circuit

and will constitute a decrease in the telephone current. Diagrammatically the action is as indicated in Fig. 9.

Oscillograms bearing on these actions were obtained in the manner indicated in Fig. 10. Oscillations were set up by the discharge of the condenser C through the

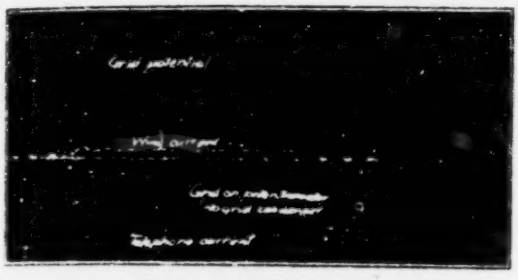

FIG. 11—OSCILLOGRAM OF ACTION AS A DETECTOR

inductance L_1 which was coupled with the inductance L of the tuned grid circuit. To permit the use of an ordinary General Electric oscillograph, an oscillation frequency of about fifty cycles per second and a group frequency of two or three cycles were employed. The action of the audion is the same regardless of frequency, provided that the circuit constants are suitably modified to fit the frequency employed. In this case the oscillation frequency of the circuit CL was fifty cycles and the circuit L_1 was accordingly tuned to the same frequency. The capacity of C was selected to correspond to the low frequency employed. Figs. 11 and 12 show oscillograms taken as indicated in Fig. 10, with the grid potential adjusted respectively to the lower and upper bends of the operating characteristic.

It will be observed that the telephone current reaches in Fig. 11 its maximum value, and in Fig. 12 its minimum value, when the oscillating current has almost died away. This effect would be shown more plainly with a higher oscillation frequency, but even at the frequency used it is quite evident.

To make use of the "valve" action between hot and cold electrodes for the detection of high-frequency oscillations a connection as shown in Fig. 13 is used.

In this case a condenser C_1 is inserted somewhere in the circuit between the grid and filament to prevent the flow of a continuous current between them, and the grid is therefore left free to assume a potential determined by its position with respect to the filament and wing. Usually this will be somewhere near the center

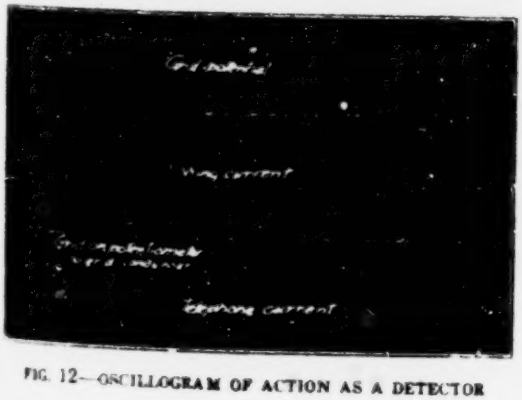

FIG. 12—OSCILLOGRAM OF ACTION AS A DETECTOR

of the operating part of the curve of Fig. 1; that is, near point P. Now the action for incoming oscillations, as far as the closed oscillating circuit, filament, grid and condenser C_1 are concerned, is identical with the rectifying action of the Fleming valve. An incoming wave train sets up oscillations in the closed circuit LC which are rectified by the "valve" action of the filament and grid, and the rectified current is used to charge the condenser C_1. Electrons pass readily enough

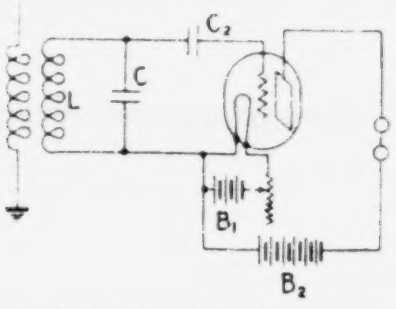

FIG. 13—USE OF AUDION AS A "VALVE"

into the grid but cannot easily escape therefrom, and a negative charge is built up on the side of the condenser connected to the grid. The negative charge thus imparted to the grid cuts down the flow of electrons from the filament to the wing, producing a decrease in the wing and telephone currents. At the end of a wave

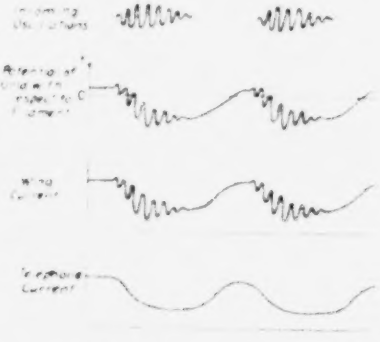

FIG. 14—ACTION OF AUDION AS A "VALVE"

train the charge in C_1 gradually leaks off and the wing current returns to its normal value. The charge and discharge of this condenser take place in the manner indicated in Fig. 14.

One group of oscillations produces a single low-frequency variation (decrease) in the telephone current

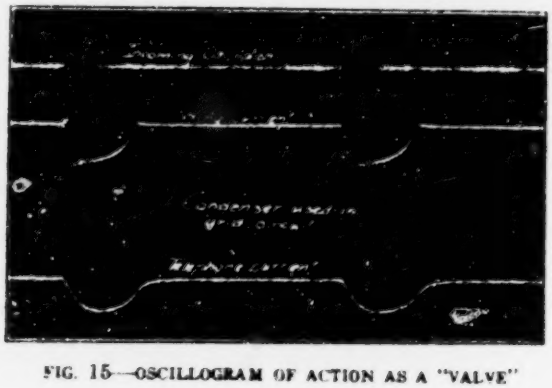

FIG. 15—OSCILLOGRAM OF ACTION AS A "VALVE"

and a series of wave trains produces a corresponding series of low-frequency variations in the telephone current. In Fig. 15 is shown an oscillogram of the behavior of the audion when the "valve" action is employed for the detection of oscillations.

With the means at hand it was impossible to ascertain the variations of the grid potential, as the leak introduced by connecting the oscillograph to the grid would destroy the cumulative action in the grid condenser. The grid potential, however, varies in exactly the same manner as the wing current. It will be seen that the fundamental detecting action is that of a valve, the high-frequency oscillations being rectified between the filament and grid, thereby causing a charge to accumulate on the grid and in the grid condenser. The charged grid then exerts a relay or trigger action on the wing current so that the audion is at once a rectifier and an amplifier. A somewhat similar combination of rectifying and amplifying actions occurs in the arrangement shown in Fig. 7. The action of the audion is being further studied by Prof. Morecroft and the writer in the research laboratory in electro-mechanics, Columbia University, and the results of these investigations will soon be published.

High-Potential Voltmeter Based on Corona Pressures

Striving by experiment to determine the relation between the corona current and the increase in air pressure which occurs if direct-current corona takes place in an inclosed space, members of the physics department of the University of Illinois, Urbana, have hopes of being able to construct a high-potential voltmeter based on this pressure phenomenon. Professor Jacob Kunz, in describing some of the experiments before the American Physical Society, stated that the tests covered potentials ranging from 3000 volts to 15,000 volts and that manometer deflections as great as 25 cm had been observed. Professor Kunz emphasized the fact that the pressure noted was not due to heating of the air, for the liquid used in the manometer responded instantly upon the application of potential. Curves plotted between potential and pressure from data obtained thus far approximate very nearly to straight lines.

The Electron Theory and Metallic Selenium Crystals

Since the usual free-electron hypothesis does not offer an explanation of (1) the increase of light sensitiveness with pressure, proportional to the conductivity of metallic selenium crystals in the dark, (2) why the change of conductivity by pressure or electrical fields is limited to the region of the crystal under stress, and (3) why the increase of light sensitiveness is limited to the region under pressure and is practically unlimited as to what region of the crystal is illuminated, Prof. F. C. Brown, Iowa State University, Iowa City, has proposed a modified form of the electron theory to satisfy all the fundamental experiments thus far recorded. This new view supposes that a large portion of the conducting electrons in the crystal are ordinarily fixed in the crystal structure in varying degrees of stability. When an electric field is established across the crystal a certain average number of these fixed electrons is rendered unstable or free. The divergence from the usually accepted notion is the conception that these electrons remain free only for a relatively short interval of time. Thus in these crystals the current increases with voltage more rapidly than is required by Ohm's law.

The effect of the increase of pressure is to lessen the degree of the stability, so that the mean interval before the recombination of the electrons is increased. "Obviously," says Professor Brown, "this seems to explain satisfactorily the increased light sensitiveness with increased pressure, and also the exact proportionality observed. It also explains the limitation of the increase to the region of the crystal under pressure. The transmitted light action observed by Prof. L. E. Sieg and myself is probably a mechanical disturbance propagated in the crystal, and enters into this theory only as the disturbance keeps electrons out of their fixed positions. If it were not for this rapid recombination of the electrons, the change of conductivity by pressure or electrical forces should be noticeable throughout a given crystal structure."

In closing his remarks, which were made before the American Physical Society at Chicago, Professor Brown suggested that a study of the conductivity changes very near the region of applied pressure might give some information as to the rate of recombination of the electrons.

Valuation in Houston, Tex.

Messrs. James E. Allison & Company, of St. Louis, Mo., have submitted a report on the rate case of the Houston (Tex.) Lighting & Power Company. They represented the company and reported on the capital now invested in the property and entitled to a return. In the letter of transmittal they say that they were aware that the report was to be submitted to the consideration of the Mayor and commission of the city of Houston in connection with a contemplated regulation of rates. A report on the property has been made by Messrs. Lyndon & Elrod, representing the Mayor of Houston.

In stating that valuation for rate making is comparatively new, the report says that the Wisconsin commission "is the one which is in great part responsible for the adoption of theoretical depreciation, and it is a very curious commentary on the theory of its members put forth in the early part of their work that while in nearly all of their cases they figure out the depreciated value, yet when they come actually to assign the amount of capital entitled to returns, the effect of depreciation cannot always be traced clearly in their announced result. The commission, while it has not yet admitted the error of applying this theory, has generally greatly raised the figures of its valuations as not to bring the results very seriously in question. There seems to have been what may be called an instinctive recognition of a just amount which has often been assigned in the commission's reports without making it very clear just how it was arrived at.

"Notwithstanding that by such methods of arriving at practical justice the Wisconsin commission has preserved itself from bringing about an impossible state of affairs in that State, yet its doctrine, which it does not always follow, has gone forth and has been adopted in many other places without that careful analysis which should have been given it. The consequence is that while Wisconsin has in some quarters gained a reputation for fair treatment of its utilities and may have so far escaped complete stagnation in utility enterprises, other localities which have followed the doctrines of Wisconsin without following its practice are already beginning to feel the effect of a theory of regulation under which private capital will not enter the public service."

An appendix to the report includes papers on the subject of depreciation by Mr. James E. Allison, Prof. Allyn A. Young, Cornell University; Prof. J. Laurence Laughlin, University of Chicago; Prof. W. F. Gephart, Washington University, and Prof. Lewis H. Haney, University of Texas.

Plaintiff's Exhibit 241.

in which λ is the frequency, e is the base of the natural logarithms and I_0 is the "initial amplitude" when $t = 0$.*

Fig. 16 shows the decrease in amplitude per cycle for different decrements, while in Table IV the oscillation curves have been drawn out for various decrements.

d. It follows from *a* that the Bjerknes decrement can be determined from the ratio of the energy lost in one cycle to that transferred in the same cycle. Hence substituting I for $I_{av.}$ we have

$$d = \frac{\frac{1}{2}RI^2T}{LI^2} = \frac{R}{2L}T = \frac{R}{2N_\lambda L} \qquad (4)$$

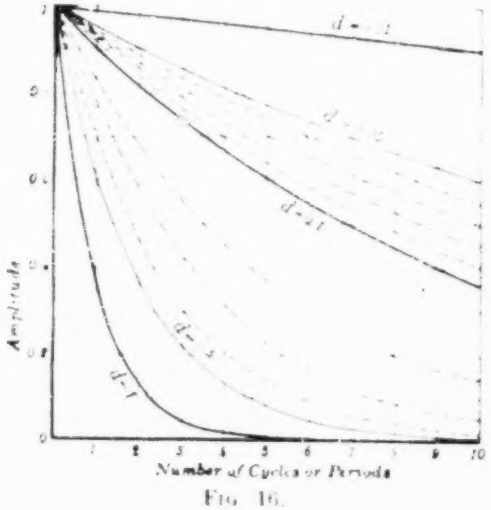

Fig. 16.

or replacing T by $2\pi\sqrt{LC}$ (Art. 8*a*) we have

$$d = \pi R\sqrt{\frac{C}{L}}$$

or from the foot-note in Art. 8*a*

$$d_1 = 2\pi^2 N_L \frac{RC}{\lambda}.$$

9. Condenser Circuit with Spark Gap. Damping due to Spark. *a.* The curves A_1 and A_2 of Fig. 17 are the amplitude curves of condenser circuits containing a spark gap (J. Zenneck) obtained with the Braun Tube. A_1 being for a circuit of very low, A_2 for one with higher ohmic resistance. Comparison with Fig. 16 shows a marked difference from the cases in which the damping is due to heat loss only. The amplitude

Patented August 19, 1902.

UNITED STATES PATENT OFFICE.

JOHN STONE STONE, OF CAMBRIDGE, MASSACHUSETTS, ASSIGNOR TO WILLIAM W. SWAN, TRUSTEE, OF BROOKLINE, MASSACHUSETTS.

SPACE TELEGRAPHY.

SPECIFICATION forming part of Letters Patent No. 707,976, dated August 19, 1902.

Application filed November 18, 1901. Serial No. 82,844. (No model.)

To all whom it may concern:

Be it known that I, JOHN STONE STONE, a citizen of the United States, and a resident of Cambridge, in the county of Middlesex and State of Massachusetts, have invented a certain new and useful Improvement in Space Telegraphy, of which the following is a specification.

My invention relates to the art of transmitting intelligence from one station to another by means of electromagnetic waves without the use of wires to guide the waves to their destination; and it relates more particularly to the system of such transmission in which the electromagnetic waves are developed by producing electric vibrations in an elevated conductor, preferably vertically elevated.

In my Letters Patent Nos. 714,756 and 714,757, granted December 2, 1902, I have described a system of selective space telegraphy in which a sonorous or persistently-oscillating circuit is associated with an elevated transmitting-conductor for developing in said conductor forced simple harmonic electrical oscillations. The forced simple harmonic electrical oscillations thus developed in the elevated conductor cause the radiation of simple harmonic electromagnetic waves, which, to distinguish them from waves guided to their destination by wires, I have termed "free or ungoided electromagnetic waves," although the earth, water, or other natural media over which they pass exerts a guiding influence upon them. In said Letters Patent I have also described a receiving system consisting of a resonant circuit attuned to the frequency of the transmitted waves and associated with an elevated receiving-conductor. I have furthermore described means whereby the system consisting of a complex of circuits is reduced to the equivalent of a system the circuits of which are the equivalent of circuits having a single degree of freedom, said means broadly consisting of an auxiliary inductance for neutralizing the effect of the mutual inductance between the sonorous circuit and the elevated transmitting-conductor or between the resonant circuit and the elevated receiving-conductor, said inductance being supplied by auxiliary coils or by the windings of the coil which associates the sonorous circuit with the elevated conductor.

In the drawing, which accompanies and forms a part hereof, the figure represents in diagram a transmitting system embodying my invention.

In the figure, V is an elevated conductor connected to earth at E. V I E is an elevated conductor system. M M' are transformers. I I' are respectively the primary and secondary windings of the transformer M. C C' are condensers. L is an inductance. S is a spark-gap. A is an alternating-current generator or other source of periodically-varying electromotive force. *k* is a key.

For the construction of parts and the operation thereof reference may be had to my hereinbefore-mentioned Letters Patent.

It has long been known that in spark-producing devices—such as static machines, Ruhmkorff coils, &c.—the spark is made larger or "fatter"—*i. e.*, that it has more energy—if a condenser be connected across the terminals of a spark-gap. Such use of a condenser in wireless-telegraph transmitting apparatus has been described by Dr. Mavin Tietz in the *Elektrotechnische Zeitschrift*, Vol. 19, No. 33, August 18, 1898, page 562, and a condenser for this purpose has been shown in Patents Nos. 706,735 and 706,739, dated August 12, 1902, and in Patent No. 711,130, dated October 14, 1902.

I have found it advantageous to connect across terminals of the spark-gap S of the sonorous circuit S C I, L a large condenser C' for the purpose of increasing the size of the spark and for increasing the energy of the disruptive discharge of the condenser C across this gap and also to form a path of low impedance to the electrical oscillations resulting from said disruptive discharge of the condenser C. As I have explained in my Letters Patent hereinbefore referred to, the condenser C in the oscillation-circuit S C I, L should be devoid of dielectric hysteresis if the oscillations developed in said circuit are to be accurately simple harmonic oscillations, and for this purpose the condenser C may

ductor of the period of the fundamental of said elevated conductor. The effect may be roughly compared to a stretched cord in a viscous medium vibrated by means of a tuning-fork. Forced vibrations are thereby developed in the stretched cord which are of frequency corresponding with that of the tuning-fork irrespective of the fundamental or natural period of the cord; but if the fundamental of the cord (which corresponds in this analogy to the elevated conductor system described herein) corresponds with the period of the tuning-fork (which corresponds in this analogy to the sonorous circuit associated with the elevated conductor) it will be found that the amplitude of vibrations executed by the cord are greater, other things being equal, than they would be without such correspondence in period.

I claim

1. In a system for developing free or unguided simple harmonic electromagnetic signal-waves of a definite frequency, an elevated-conductor system the fundamental of which has a period equal to the period of the waves to be transmitted, and means for developing the enforced simple harmonic electric vibrations of corresponding frequency.

2. In a system of space telegraphy an elevated conductor, a sonorous circuit, associated therewith and containing a condenser, and a condenser of capacity large as compared with the capacity of the condenser in said sonorous circuit, connected across the terminals of a spark-gap in said sonorous circuit.

3. In a system of space telegraphy, a sonorous circuit adapted to develop electric vibrations of a definite frequency, and elevated-conductor system associated therewith, the fundamental period of which is the same as the period of said sonorous circuit, and means for swamping the effect of the mutual inductance between said sonorous circuit and the elevated-conductor system.

4. In a system of space telegraphy, an elevated conductor, a sonorous circuit associated therewith and a condenser connected across the terminals of a spark-gap in said sonorous circuit.

5. In a system for developing free or unguided simple harmonic electromagnetic signal-waves of a definite frequency, an elevated-conductor system and a sonorous circuit associated therewith and adapted to develop simple harmonic electrical vibrations corresponding in period with the fundamental period of said elevated-conductor system.

6. In a system of space telegraphy, a transmitting system comprising a persistently-oscillating circuit, a good radiating-circuit, the fundamental period of which is equal to the period of said persistently-oscillating circuit, and means whereby said transmitting system is reduced to the equivalent of a system of a single degree of freedom.

7. In a system of space telegraphy, a transmitting system comprising a persistently oscillating circuit, a good radiating-circuit, attuned as to its fundamental to the period of said persistently oscillating circuit, and an auxiliary inductance for swamping the effect of the mutual inductance between said circuits.

8. As a means for developing electrical oscillations, a sonorous circuit containing a spark-gap and a condenser of large capacity connected across the terminals of said spark-gap by conductors of low impedance.

9. In a system of space telegraphy, an elevated conductor, a sonorous circuit, containing a spark-gap, associated therewith and a condenser connected across the terminals of said spark-gap by conductors of low impedance.

10. In a system of space telegraphy, an elevated conductor, a sonorous circuit, containing a spark-gap, associated therewith and a circuit consisting of large capacity and low resistance for affording a path of low impedance to the electrical oscillations developed in said sonorous circuit, connected across the terminals of said spark-gap.

11. In a system of space telegraphy, a transmitting system comprising a persistently-oscillating circuit containing the primary of a step-up transformer, a good radiating-circuit containing the secondary of said transformer, the fundamental period of said radiating-circuit being equal to the period of the persistently-oscillating circuit, and means whereby said transmitting system is reduced to the equivalent of a system each of whose circuits has a single degree of freedom.

12. In a system of space telegraphy, a sonorous circuit adapted to develop electrical vibrations of a definite frequency, an elevated-conductor system associated therewith by means of a step-up transformer, the fundamental of the elevated-conductor system being equal to the period of the persistently-oscillating circuit, and means for swamping the effect of the mutual inductance between said sonorous circuit and said elevated-conductor system.

13. In a system for developing free or unguided, simple harmonic, electromagnetic signal-waves of definite frequency, an elevated-conductor system the fundamental of which has a period equal to the period of the waves to be transmitted, means for developing simple harmonic electrical oscillations of corresponding frequency and means for impressing said electrical oscillations on said elevated-conductor system at increased potential.

14. In a system of space telegraphy, an elevated conductor, the fundamental of which has a period equal to the period of the waves to be transmitted, a sonorous circuit associated with said elevated conductor and adapted to develop electrical oscillations of corre-

30932

sponding period and a condenser or other capacity connected across the terminals of the spark-gap of said sonorous circuit.

15. In a system of space telegraphy, a persistently-oscillating circuit, and a good radiating-circuit, attuned as to its fundamental to the period of said persistently-oscillating circuit, in combination with means for increasing the amplitude of the electrical oscillations developed in said persistently-oscillating circuit.

16. In a system of space telegraphy, a persistently-oscillating circuit containing a spark-gap, a good radiating-circuit, attuned as to its fundamental to the period of said persistently-oscillating circuit, and a condenser connected across the terminals of said spark-gap.

17. In a system of space telegraphy, a sonorous circuit, a good radiating-circuit, attuned as to its fundamental to the period of said sonorous circuit, and means for impressing the oscillations created in said sonorous circuit upon said good radiating-circuit at increased potential, in combination with means for increasing the persistency of the oscillations developed in said sonorous circuit.

In testimony whereof I have hereunto subscribed my name this 23d day of November, 1903.

UNITED STATES PATENT OFFICE.

LEE DE FOREST, OF NEW YORK, N. Y.

STATIC VALVE FOR WIRELESS-TELEGRAPH SYSTEMS.

No. 823,402 Specification of Letters Patent. Patented June 12, 1906.

Application filed December 3, 1905. Serial No. 291,067.

To all whom it may concern:

Be it known that I, LEE DE FOREST, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented a new and useful Improvement in Static Valves for Wireless-Telegraph Systems, of which the following is a specification.

My invention relates to wireless-telegraph receiving systems, and more especially to apparatus and circuit arrangements whereby atmospheric electricity or static disturbances may be minimized or elimnated.

It is well known that the receiving antennæ of commercial wireless-telegraph systems often become charged with static electricity by such natural causes as the passage of charged clouds in the vicinity of the antennæ, lightning discharges which may be even far distant from the receiving-station, the impingement upon the antennæ of winds, especially hot winds, laden with ionized air, &c. Very often such static charges so accumulated by the antennæ seriously interfere with the reception of signals transmitted by electromagnetic waves from distant stations, and sometimes, especially in tropical and semitropical climates, these static effects become so pronounced as to entirely prevent the reception of such signals.

The object of the present invention is to provide means for preventing by static valves or leaks any deleterious effect on the reception of signals by static or other natural or artificial electrical forces.

My invention may best be understood by having reference to the drawings which accompany and form a part of this specification and which conventionally represent various forms of static valves or leaks which I have found efficient for carrying out the hereinbefore-stated objects, although it is to be understood that I do not limit myself to the specific embodiments of my invention shown in said drawings, inasmuch as many other embodiments thereof may be devised by those skilled in the art without departing from the spirit of my invention.

In the drawings, Figure 1 represents a wireless-telegraph receiving system provided with two forms of static valve or leak. Fig. 2 represents a wireless-telegraph receiving system provided with an electrolytic static valve or leak. Fig. 3 represents a wireless-telegraph receiving system in which an iron spiral is employed as a static leak. Fig. 4 represents a wireless-telegraph receiving system in which a flame is used as a static valve or leak. Fig. 4ª shows a modification of the device illustrated in Fig. 4, and Fig. 5 represents a wireless-telegraph receiving system in which heated mineral wool or the like is employed as a static leak.

For the purpose of more fully disclosing the present invention I have shown in Fig. 1 two embodiments of the same applied to a receiving system of my invention which comprises a loop antenna, although, as shown in Figs. 2, 4, and 5, the present invention is not limited to any particular kind of receiving system, being capable of application to any type of receiving system.

In Fig. 1, A is a loop antenna, the two sides of which are adjustably connected to the inductances L L′, which are connected to earth at E. Across any desired portion of the inductance L the tuned receiving-circuit C R L, including the variable condenser C and responder or oscillation-detector R, is adjustably connected, and by means of the adjustable contact *m* and said variable condenser C the natural period of said tuned receiving-circuit is made equal to that of the loop antenna while by means of the adjustable contacts *n* and *o* the natural period of said loop antenna is made equal to that of the electromagnetic waves to be received. Across the terminals of the responder R is connected the local receiving-circuit, including the telephone T and any desired portion of the potentiometer resistance P, which regulates the potential of the battery B to be impressed upon the responder. A static leak V or V′ is connected between the earth E and any suitable point *a* or *b* of the antenna located between the top of the antenna and the adjustable contacts *n* or *o*, and preferably near said adjustable contacts. One static leak only may be employed with a loop antenna, as shown in Fig. 3, and if two are used they may be of the same or of different types. If the receiving system is provided with an open antenna, only one static leak is used, as shown in Figs. 2, 4, and 5.

A variety of devices may be used as static leaks, and I shall now specifically describe the six devices V, V′, V″, V‴, V⁗, V⁗′, and V⁗″, shown in the drawings, although it is to be understood that many other devices may be employed.

V is a static valve or leak consisting of an electrolytic cell comprising an electrode F,

2680

which may form a cup of aluminium, tantalum, iron, or other suitable metal an electrode D of carbon, platinum, or other suitable material and an electrolyte cooperating with said electrodes and consisting of aluminium phosphate, caustic soda or potash, or any other suitable chemical solution. A cell so constructed has the well known property of permitting electric currents of given polarity to pass through it in one direction for example from the carbon electrode to the aluminium electrode more readily than in the opposite direction in short, such a cell is an electric valve or asymmetric resistance.

The reversing-switch S cooperates with the contacts 1 and 3, which are connected to the electrode D, and the contact 2, which is connected with the cup F, and enables the operator to connect either the electrode D to the antenna and the electrode F to earth or the electrode F to the antenna and the electrode D to earth. For the purpose of describing the operation of the cell V it will be assumed that the electrode D, which is connected to the antenna in the position of the switch shown in Fig. 1, is carbon and that the electrode F, which is connected to earth in said position of the switch is aluminium. With a cell so constructed and so connected a positive charge of electricity developed in the antenna will readily pass through the cell to earth and will therefore be prevented from affecting the responder R, but a negative charge of electricity developed in the antenna will not pass through the cell to earth and might, therefore, affect the responder R. If with the switch set in the position shown in Fig. 1 the operator should detect the effects of static disturbances, he would throw the switch so as to coöperate with the contacts 2 and 3, thereby connecting the aluminium electrode F to the antenna and the carbon electrode to earth, in which position of said switch a negative electric charge developed in the antenna would pass to earth. Thus the position of the switch must be determined empirically by the operator in accordance with observed phenomena.

It will be noted that when the switch is set so that the cell will conduct a positive charge to earth the positive half waves developed in the antenna by the electromagnetic waves to be received will also be conducted to earth and will not assist in producing signals and that when the connections of the cell are reversed so as to conduct negative electric charges to earth the negative half-waves developed in the antenna by said electromagnetic waves will also be conducted to earth, so that the static valve results in wasting approximately half the received energy. I have found, however, that the remaining energy absorbed by the antenna from the electromagnetic waves is sufficient to operate the responder, and I have been enabled with a system provided with said static valve employed as above set forth to receive signals under conditions of static disturbance which otherwise would have rendered such reception impossible.

It will be noted that if, as indicated in Fig. 1, two static valves are employed with one antenna, each must be connected so as to pass currents or charges of the same polarity, for if they were connected so as to pass currents or charges of opposite polarities one-half the energy of the waves would pass to earth by way of one valve and the other half by way of the other. Generally but one valve will be sufficient, and while it may be connected to earth from either the point *a* or the point *b* (see Fig. 1) it is preferred to connect it to earth from the point *a*, so that its circuit will form a shunt around that portion of the antenna with which the responder circuit is associated.

The static valve shown at V' in Fig. 2 is another form of electrolytic asymmetric resistance consisting of two cups Q Q of insulating material, the cup Q containing two electrodes D D of the same materials as above set forth in connection with the static valve V of Fig. 1 and also containing the electrode F of the same materials as the electrode F of the said valve V, and the cup Q containing one electrode D and two electrodes F F of the same materials, respectively, as the electrodes of the cup Q.

The operation is as follows: When the receiving operator perceives that static effects are interfering with the reception of signals he throws the switch S' over to the contacts 7 8 of the device Q and if the static effects are positive they will pass to earth E' by way of contact 7, carbon electrode D, and aluminium electrode F, while the negative half waves developed in the antenna by the electromagnetic signal-waves will pass to earth E by way of the contact 7, electrode D, the electrolyte, electrode D, contact 8, and inductance L, thereby causing oscillations in the tuned receiving-circuit C R L and operating the receiver. If, however, the said static effects continue to interfere with the reception of signals when the device Q is connected in circuit as above set forth, the receiving operator will know that the static effects are negative and will therefore proceed to throw the switch over to the contacts 9 10, in which case said negative static effects will pass to earth E' by way of the contact 9, aluminium electrode F, and carbon electrode D, while the positive half-waves developed in the antenna by the electromagnetic signal-waves will pass to earth E by way of the contact 9, electrode F, the electrolyte, electrode F, contact 10, and inductance L, thereby creating oscillations in the tuned receiving-circuit C R L and operating the receiver.

It will be seen in view of the foregoing that

2681

any electrical rectifier, asymmetric resistance, or "electric valve," electrolytic or otherwise, may be utilized in carrying out the above-stated objects of my invention, and I shall now describe several forms of electric valve that are not electrolytic in nature.

The device V', (shown in Fig. 1,) connected between the antenna at the point *b* and earth, is an asymmetric resistance or electric valve which has been fully described by J. A. Fleming in a paper published in the *Proceedings of the Royal Society of London*, March 16, 1905, to which reference may be had for a more complete description thereof than need be set forth herein. Suffice it to say that the exhausted glass vessel Q'' contains the filament F', heated to incandescence by the battery B', and a metal cylinder D', which surrounds said filament F'. This type of valve passes positive electricity from the cold terminal D' to the heated terminal F' more readily than in the opposite direction, and hence when the switch S' makes contact, as shown in Fig. 1, with the contacts 5 and 6 positive static effects will pass to earth by way of the elements D' and F' of said valve, while if the connections be reversed by throwing the switch so as to contact with 4 and 5 negative static effects will pass to earth by way of the elements F' and D' of said valve.

In Figs. 4 and 4ª the valves V^IV and V^V depend upon somewhat the same principle as the valve V'. In these figures H is a lamp or Bunsen burner, the flame of which may be made more conducting by the addition of sodium or other salts, and J is a conductor placed near said flame. M is a bunch of asbestos or mineral wool which may be attached to said conductor J. In these devices positive electricity passes more readily from the element J to the flame, and hence to earth E', than in the opposite direction. S''' is a reversing-switch whose function is the same as that of the switch S.

In Fig. 5 the device M' consists of mineral wool or asbestos placed between two plates and heated by the lamp H. This device is practically non-conducting when cold, but becomes a partial conductor when heated. The oscillations developed in the antenna by the electromagnetic signal-waves will have but little tendency to pass to earth by way of the shunt *a'* M' E', but heavy static charges induced in the antenna have an effect on the device M' somewhat analogous to the phenomenon of coherence (although it is not a contact device) in that they increase the conductivity of said device, so that the latter becomes a very efficient static leak. The passage of the heated gases from the lamp H through the fibrous material of the device M' maintains said device in its sensitive high-resistance condition, and thereby prevents the shunting around to inductance L of the oscillations intended to operate the responder.

In Fig. 3 I have shown still another static leak V^VI, which I have effectively employed for the purpose of carrying my invention into effect. In this figure the arrangement of receiving-circuits is the same as in Fig. 1, and from the point *a* I connect to earth E a shunt circuit including the adjustable inductance-coil, I of iron or other paramagnetic material or of a non-magnetic material plated with a paramagnetic material or of a non-magnetic material having a paramagnetic core. Such an inductance opposes enormous impedance to the passage of the high-frequency oscillations developed in the receiving system by the electromagnetic signal-waves, but offers but little impedance to the passage of the slow-frequency or practically unidirectional currents resulting from the static charges induced in said system by atmospheric electricity, and hence eliminates the effect of said currents on the receiver.

By the term "static valve" as used in the specification and claims of this application I desire to be understood as meaning means offering greater opposition to electric currents of one character than to electric currents of different character—such, for example, as the asymmetric resistances described in connection with Figs. 1, 2, 4, and 4ª, the spiral I, described in connection with Fig. 3, and the coherer-like device M, described in connection with Fig. 5; but it is to be understood that the particular devices hereinbefore specifically described are merely examples of a few of the static valves which may be employed for the purposes of the present invention.

I claim—

1. In a wireless-telegraph receiving system, the combination with an oscillation-detector of an electrolytic static valve.

2. In a wireless-telegraph receiving system, an oscillation-detector and an electrolytic static valve so associated therewith as to protect the same from static effects.

3. In a wireless-telegraph receiving system, a receiving-antenna, an inductance included therein, a tuned receiving-circuit associated with said inductance, an oscillation-detector in said tuned receiving-circuit, and means offering greater opposition to electric currents of one character than to electric currents of different character connected between the earth and a point in said antenna above the point of connection of said inductance to said antenna.

4. In a wireless-telegraph receiving system, an oscillation-detector, and means offering greater opposition to electric currents of one polarity than to electric currents of the opposite polarity so associated with said detector as to protect said detector from the effects of the currents of that polarity to which said means offers the greater opposition.

5. In a wireless-telegraph receiving system, an oscillation-detector, and an asymmetric resistance so associated therewith as to protect the same from static effects.

6. In a wireless-telegraph receiving system, an oscillation-detector, a static valve connected therewith and means for reversing the connections of the terminals of said static valve with said oscillation-detector.

7. In a wireless-telegraph receiving system, an oscillation-detector, an asymmetric resistance so connected therewith as to protect the same from static effects, and means for reversing the connections of the terminals of said asymmetric resistance with said oscillation-detector.

8. In a wireless-telegraph receiving system, an oscillation-detector, and an electrolytic asymmetric resistance so associated therewith as to protect the same from static effects.

9. In a wireless-telegraph receiving system, an oscillation-detector, an electrolytic asymmetric resistance so connected therewith as to protect the same from static effects, and means for reversing the connections of the terminals of said electrolytic asymmetric resistance with said oscillation-detector.

10. In a wireless-telegraph receiving system, a receiving-antenna, an oscillation-detector associated therewith, and an electrolytic static valve connected between the earth and a point in said antenna above the point of association of said detector with said antenna.

11. In a wireless-telegraph receiving system, a loop antenna, an inductance included in each side thereof, an oscillation-detector associated with said loop antenna, a connection from each side of said loop antenna around each said inductance to earth and a static valve in each said connection.

12. In a wireless-telegraph receiving system, a loop antenna, an oscillation-detector associated therewith, a static valve associated with each side thereof, and means for reversing the connections of each said static valve with its respective side of said loop antenna.

13. As a static valve for a wireless-telegraph receiving system, an electrolytic asymmetric resistance.

14. As a static valve for a wireless-telegraph receiving system, an asymmetric resistance.

15. In a wireless-telegraph receiving system, a loop antenna, an inductance included in each side thereof, an oscillation-detector associated with said loop antenna, a connection from one side of said loop antenna around one inductance to earth and a static valve in said connection.

16. In a wireless-telegraph receiving system, a loop antenna, an inductance included in each side thereof, a tuned receiving-circuit associated with said loop antenna, an oscillation-detector in said tuned receiving-circuit, and a static valve connected between the earth and a point in said antenna above the point of connection of said inductance to said antenna.

17. In a wireless-telegraph receiving system, a receiving-antenna, an inductance included therein, a tuned receiving-circuit associated with said inductance, an oscillation-detector in said tuned receiving-circuit, and a static valve connected across the terminals of said inductance.

In testimony whereof I have hereunto subscribed my name this 6th day of December, 1905.

UNITED STATES PATENT OFFICE.

MICHAEL I. PUPIN, OF NORFOLK, CONNECTICUT, AND EDWIN H. ARMSTRONG, OF YONKERS, NEW YORK.

ELECTRIC-WAVE TRANSMISSION.

1,334,165. Specification of Letters Patent. Patented Mar. 16, 1920.

Application filed September 17, 1915. Serial No. 51,151.

To all whom it may concern:

Be it known that we, MICHAEL I. PUPIN, a citizen of the United States, residing in Norfolk, county of Litchfield, State of Connecticut, and EDWIN H. ARMSTRONG, a citizen of the United States, residing in Yonkers, county of Westchester, State of New York, have invented certain new and useful Improvements in Electric-Wave Transmissions; and we do hereby declare the following to be a full, clear, and exact description of the invention, such as will enable others skilled in the art to which it appertains to make and use the same.

This invention relates to the production of a negative resistance reaction by means of a system of circuits containing a local source of electrical power with means for controlling it, and the application of this negative resistance reaction to the compensation of the resistance reaction of electrical conductors in order to make them responsive to sustained electrical waves of a predetermined frequency and not responsive to electromotive forces of a disturbing character. The apparatus described here is, briefly stated, a new form of resistance compensator operating in a generic sense similarly to the resistance compensator described by Michael I. Pupin in his copending application, Serial No. 51,150 filed September 17, 1915.

Referring to the diagrams which form a part of our specification, Figure 1 illustrates a system for producing the aforesaid negative resistance reaction, and Figs. 2^a and 2^b show curves of its resistance and reactance characteristics for various frequencies. Fig. 3 shows a method of applying the resistance compensator to reduce the effective resistance of a conductor. Fig. 4 shows a system of magnifying the negative resistance reaction produced by the system of Fig. 1 by means of a magnifying shunt placed around the main conductor of the compensator, and Fig. 5 illustrates the resistance and reactance characteristics obtained with a shunted compensator. Fig. 6 illustrates the method of applying the shunted compensator to the tuning of a conductor. Fig. 7 represents a compensator consisting of a plurality of parts connected in cascade system for the purpose of producing very large values of negative resistance. The characteristics of this system are illustrated by the curves of Fig. 8. Fig. 9 illustrates the application of the resistance compensator to a wireless antenna.

In the particular arrangement illustrated in Fig. 1, an electrical valve 1 is coupled with the main conductor 2, 3, 4, 5 on the input side by means of the circuit 6, 7, 8, and on the output side by the circuit 9, 10, 11, 12. The electrical valve illustrated here is the well known vacuum tube containing a hot cathode 13 and a cold anode 9, between which a direct current flows, and a third electrode or "grid" 14 between them modifying the normal direct current between the hot cathode and the cold anode. The external impulses are conveyed to the valve by the circuit 6, 7, 8, which will be referred to as the "exciting circuit." By adjusting the constants of the exciting circuit 6, 7, 8, with respect to the frequency of the incoming waves, the excitation of the valve is regulated. The other circuit 13, 12, 15, 10, 9, contains an electrical battery 10 which maintains a direct current between the hot cathode 13 and the cold anode 9. The incoming waves vary the electrical potential of the grid 14 and thereby the direct current. This variation produces an electromotive force in the main conductor 2, 3, 4, 5, by mutual induction between 4 and 12, whereby energy is transferred from the battery 10 to the main circuit. It is this transfer of energy which manifests itself through a reaction between 2, 5, which has all the properties of a negative resistance reaction. This second circuit with its battery 10 through which the electrical valve is connected to the main conductor will therefore be referred to in this specification as the "energizing circuit."

It will be seen that in the arrangements described herein we have produced results by operations which are generically similar to those of the induction motor resistance compensator described in the above mentioned Pupin application, in which the primary circuit of the induction motor receives the incoming waves and produces thereby the magnetic excitation, whereas the rotating secondary by its electromagnetic reactions transfers by expenditure of mechanical energy electrical energy to the primary and thereby produces in it a negative resistance reaction. The amount of the negative resistance reaction produced by the means employed in the present case depends upon the

relation of the constants of both the exciting and energizing circuits to the frequency of the incoming waves, and for the purpose of adjusting these constants, variable inductances 7 and 12 and capacities 8 and 11 and a variable resistance 6 are employed. In other words, these circuits are capable of tuning.

The effective resistance and the effective inductance of the system of Fig. 1 between the points 2 and 5 as measured by a Wheatstone bridge employing an alternating electromotive force of suitable frequency, may be either as in Fig. 2ª or Fig. 2ᵇ, depending on the polarity of connection of the transformers 3, 7, and 4, 12. In Fig. 2ª the maximum negative resistance in the main conductor is developed at a frequency below, and in Fig. 2ᵇ the maximum negative resistance is developed at a frequency above the frequency for which the exciting circuit when taken by itself is non-reactive.

The negative resistance reaction in the main conductor 2, 5, is produced in the system of Fig. 1 by the following operations. [illegible] the main conductor 2, 3, 4, 5, induces in the circuit 6, 7, 8, an electromotive force which charges the condenser 8 and the grid connected to it. The charged grid produces a variation in the amplitude of the plate current flowing through the inductive element 10, 15, 12, 13. The current variation then induces an [illegible] in the main conductor. [illegible] current in the main conductor and the electromotive force determines the reactions which are produced in the main conductor. If the electromotive force thus produced in the main conductor is so constituted in phase that one of its two components is in the same phase with the current in the main conductor then a resultant negative resistance reaction between 2 and 5 appears when this electromotive force component is greater than the effective positive resistance reaction of the coils 3 and 4. The value of this negative resistance reaction depends only upon the amount of current variation produced by the action of the grid 14 and upon the process of mutual induction between the main circuit and its secondaries. The law in accordance with which this value of the negative resistance reaction may be varied, and given any assigned limit, is discovered by connecting the terminals 2, 5, of the main conductor as represented in Fig. 1 into an arm of a Wheatstone bridge employing alternating electromotive force of suitable frequency and intensity. The curves illustrated by Figs. 2ª and 2ᵇ are a result of a study of this kind. In these figures, the ordinates of curve R represent the effective resistance and of curve L, the effective inductance between the terminals 2, 5, for various frequencies. It will be seen that these curves are in their main features, similar to those obtained with the induction motor compensator described in the previous application referred to. No exact general mathematical formulæ can be given which will express the relation between the effective resistance and effective reactance of the main conductor and the electromagnetic constants of the various parts of the system and the impressed frequency. But an experimental study by means of a Wheatstone bridge enables one to construct easily an empirical formula for any particular case.

To apply this negative resistance reaction to the compensation of the resistance reaction of an electrical conductor, we proceed in the manner indicated in Fig. 3. Here 16, 17, 18, is a conductor containing resistance, inductance and capacity and which is to be tuned to the frequency of an impressed simple harmonic electromotive force. The main conductor 2, 3, 4, 5, of the [illegible] compensator is placed in series [illegible] the conductor 16, 17, 18, and the [illegible] 6, 7, 8, adjusted to produce negative [illegible] between the points 2, 5, at [illegible] for which the conductor 19, 5, [illegible] selective. The value of the [illegible] resistance between 2 and 5 is adjusted to be slightly less than the positive [illegible] of the conductor 19, 2, so that the resultant effective resistance of the conductor 19, 5 is very much reduced for the correct frequency. This has been explained at greater length in the previous application referred to. The negative resistance may be varied by adjusting the coupling between 4 and 12, or 3 and 7, or by varying the power of the valve to vary the load direct current, or by varying the value of the resistance 6. As the main function of the resistance 6 is to control the steepness of the resistance curves R, in Figs. 2ª and 2ᵇ in the vicinity of their negative maxima and thereby vary the sharpness of tuning of the system, it is better to vary one of the couplings to obtain the required variation in negative resistance. The reactance of the main conductor is adjusted to zero for the same frequency by means of the inductance 16 or the condenser 18.

For the right frequency, the conductor 19, 5, therefore, has zero reactance, and an effective resistance which is only a small fraction of the resistance added to it, but for all other frequencies, both the resistance and the reactance are relatively very large. The amount of positive resistance that can be added in this way is limited by the capacity of the resistance compensator and by nothing else.

The arrangement of the present application lends itself to magnification of the resistance reaction by means of a shunt or by [illegible]

other well known means of potential magnification by transformation in the same manner as the arrangement of the Pupin application referred to, does.

This may be done by the arrangement represented by the diagram of Fig. 4. In this arrangement which is the counterpart of the arrangement of Fig. 3 of the previous application referred to above, a non-inductive shunt containing resistance 22 is placed across the conductor in which the negative resistance is produced. This conductor is provided with a series condenser 23 for the purpose of adjusting the effective reactance of the conductor. When the shunt positive resistance is made slightly greater than the shunted negative resistance, a large multiplication of the original negative resistance is obtained in the manner explained in the previous application. A shunt of 1200 ohms placed across the conductor having the characteristic of Fig. 2 gives a multiplication of above six times. The characteristic resistance and reactance curves are shown in Fig. 5.

To apply the shunted valve system for the purpose of compensating the resistance reaction of a conductor, we connect the conductor 20, 21, in series with the conductor 16, 17, 18, as illustrated in Fig. 6. The adjustments of resistance and reactance of the main conductor are made in the manner previously described for the simple resistance compensator.

Another method of producing a high negative resistance is by means of a resistance compensator consisting of a plurality of parts in cascade as depicted in Fig. 7. Two parts are shown here, but any number of parts may be used to produce any required value of negative resistance reaction in the main conductor providing due regard is paid to the proper adjustment of the phase of the mutual inductance reaction between the energizing circuit and the main conductor. The characteristics of the particular arrangement of Fig. 7 are illustrated by the curves of Fig. 8.

In the present application, as in the previous application referred to, the arrangement for producing negative resistance should preferably be such that the full value of the negative resistance cannot be produced instantaneously; that is, a certain definite length of time should elapse after the arrival of the initial impulse of a train of waves before the transient electrical state has passed into the stationary state in which the full maximum value of negative resistance is established. This length of time is determined by the duration of the transient state of the exciting circuit, and may be regulated by suitable adjustment of the resistance of this circuit which determines the rate of damping of its free oscillation.

To apply the resistance compensator to the reduction of atmospheric disturbances, we prefer to arrange the apparatus as in Fig. 9, in which a resistance compensator containing a plurality of electron discharge elements is arranged to produce in the antenna a high negative resistance reaction. The first part is connected to the antenna by means of a condenser 18 which is located at the base of the antenna and is shunted by a resistance 26 which constitutes a leakage path for electrostatic charges accumulating on the antenna. The particular advantage of the specified connection of 17, 16 and 18 is that the condenser 18 is shielded by the high resistance 17 and the inductance 16 from pulses of short duration which are unable to develop any appreciable reaction across the condenser and thereby excite the compensator. The second part of the resistance compensator is connected to the antenna through the transformer 16, 27, and an electrostatic transformer 28 or any other detecting device is inductively associated with the coil 27.

As explained in the previous application, the shunt employed for magnifying the negative resistance reaction offers a means for shielding the induction motor from the direct effects of electrical impulses. We find the same advantages are secured by the use of the shunt with the present form of resistance compensator in the manner previously described.

What we claim is:

1. In a receiving system for electromagnetic waves, a receiving conductor into which is introduced a resistance sufficiently high to screen the system effectively against disturbing electromagnetic waves impressed upon the conductor in combination with a resistance compensator consisting of an electrical power source and means for selectively transferring power from this source to the conductor by producing in the conductor a negative resistance reaction sufficiently large to compensate to any desirable limit the losses due to the dissipative resistance introduced into the receiving conductor.

2. In a wireless receiving system a wave conductor for the reception of electrical waves into which is introduced a resistance sufficiently great to make its resistance reaction large in comparison with its inductance reaction for all frequencies which are important in wireless wave transmission in combination with a resistance compensator consisting of an electrical power source and controlling means excited by the incoming waves for transferring power from the power source to the conductor to supply it with a compensating negative resistance, the resistance compensator being responsive to a sustained impressed electromotive force

and substantially unresponsive to an impressed electromotive force of short duration.

3. In a wireless receiving system a wave conductor for the reception of electrical waves into which is introduced a resistance sufficiently great to make its resistance reaction large in comparison with its inductance reaction for all frequencies which are important in wireless wave transmission in combination with a resistance compensator consisting of an electrical power source and controlling means excited by the incoming waves for transferring power from the power source to the conductor to supply it with a compensating negative resistance, the resistance compensator being selectively responsive to a sustained impressed electromotive force and substantially unresponsive to an impressed electromotive force of short duration.

4. A receiving system for electrical waves consisting of a receiving conductor with which has been associated a resistance sufficiently large to screen the system effectively against disturbing electromagnetic waves impressed upon the antenna and a resistance compensator having an exciting circuit which is connected across a condenser in series with the receiving conductor so that the direct effect of electrical impulses of short duration on the compensator is greatly reduced.

5. A receiving system for electrical waves consisting of a receiving conductor with which has been associated a resistance sufficiently large to screen the system effectively against disturbing electromagnetic waves impressed upon the antenna, a resistance compensator deriving its power from an electrical power source and connected to said conductor and a magnifying shunt across the said compensator containing a resistance of such value that the resultant negative resistance reaction of the combined circuits will be greater than the original negative resistance reaction to magnify the negative resistance reaction introduced into the main conductor and to shield the compensator from the direct effect of electrical impulses.

6. A resistance compensator consisting of a plurality of parts connected in cascade each part having an exciting circuit and an energizing circuit with an electrical power source, the exciting circuit of the first part being connected to a wave conductor, and the energizing circuit of each part being connected to the exciting circuit of the succeeding part, except the last part, the energizing circuit of which is connected to the wave conductor, and in which at least one of the exciting circuits is tuned, whereby there is selectively imparted to the wave conductor a high negative resistance reaction.

7. A resistance compensator consisting of a plurality of parts connected in cascade each part having an exciting circuit and an energizing circuit with an electrical power source, the exciting circuit of the first part being connected to a wave conductor, and the energization circuit of each part being connected to the exciting circuit of the succeeding part, except the last part, the energizing circuit of which is connected to the wave conductor, and in which at least one of the exciting circuits is tuned, and one of them having the characteristic that impulses imparted to it produce their full exciting effect after a predetermined time interval only.

8. A receiving conductor into which has been introduced a resistance sufficiently high to make its resistance reaction large as compared with its inductance reaction for all frequencies which are important in wireless wave transmission in combination with a resistance compensator consisting of a source of electrical power and means for transferring from the power source to the receiving conductor wave energy of substantially the same wave form as selected incoming waves and of potential sufficiently high to produce in the receiving conductor a negative resistance reaction which substantially compensates the losses due to the positive resistance introduced into said conductor.

In testimony we affix our signatures.

His Attorney.

UNITED STATES PATENT OFFICE.

WILLIAM C. WHITE, OF SCHENECTADY, NEW YORK, ASSIGNOR TO GENERAL ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

MEANS FOR PRODUCING HIGH-FREQUENCY OSCILLATIONS.

1,393,594. Specification of Letters Patent. Patented Oct. 11, 1921.

Application filed June 3, 1918. Serial No. 237,845.

To all whom it may concern:

Be it known that I, WILLIAM C. WHITE, a citizen of the United Seates, residing at Schenectady, in the county of Schenectady, State of New York, have invented certain new and useful Improvements in Means for Producing High-Frequency Oscillations, of which the following is a specification.

My present invention relates to the production of high frequency oscillations by means of an electron discharge relay or amplifier, and more particularly to the application of oscillations thus produced in a radio receiving system of the well-known heterodyne type.

Electron discharge devices of the type comprising an evacuated container inclosing a filamentary cathode, a plate-shaped anode and a grid, interposed between cathode and anode, are well known. Various connections have also been employed with such devices to cause them to operate to produce high frequency oscillations. In all of the connections which have previously been used, however, so far as I am aware, the same fundamental principle has been employed, that is, a portion of the amplified energy in the plate circuit of the device has been fed back to the grid circuit by some form of coupling so as to make the system self-exciting.

In carrying my invention into effect, however, I employ a materially different principle. I have found that under certain conditions with devices of this type the current in the grid circuit may have a dropping characteristic, that is, as the voltage impressed upon the grid increases the current in the grid circuit will decrease. With the proper conditions for operation a circuit having current characteristic of the type described may be so organized that oscillations will be produced therein, the essential condition for the production of oscillations being that the circuit shall contain capacity and inductance and that the resistance of the circuit shall be less than $2\sqrt{\frac{L}{C}}$ where L represents the inductance and C the capacity of the circuit. Hence in carrying my invention into effect I provide the connections necessary to render the grid circuit resonant and thus cause the production of oscillations therein. While the current in the grid circuit is in all cases comparatively small and hence the amplitude of the oscillations produced will be small the amplifying effect of the device will cause oscillations of much greater amplitude to be produced in the plate circuit. The maintenance of the oscillations, however, will be entirely independent of any coupling between the two circuits.

In utilizing my invention in a radio receiving system of the heterodyne type I produce in the grid circuit of the device oscillations of slightly different frequency from those which are to be received. The received oscillations may also be impressed upon the grid circuit and the two sets of oscillations be combined in that circuit to produce what are technically known as "beats." These beats will be reproduced in the plate circuit of the device and produce an audible response in the usual telephone receiver which is included in the plate circuit.

The novel features which I believe to be characteristic of my invention are set forth with particularity in the appended claims. The invention itself, however, both as to its organization and method of operation will best be understood by reference to the following drawing in which Figure 1 illustrates diagrammatically the connections which may be employed in carrying my invention into effect, and Fig. 2 shows a characteristic curve of the current in the grid circuit of an electron discharge device which is so constructed and adjusted as to be suitable for carrying out my invention.

In the system illustrated in Fig. 1 I have indicated an electron discharge device 1 having the usual filamentary cathode 2, an anode 3 which may be plate shaped as shown or of any other desired form and a discharge-controlling grid 4 inclosed in a well evacuated receptacle. The grid circuit of this device includes an inductance 5 and a variable capacity 6. A battery 7 is provided for applying to the grid a potential at which the operation of the device may be suitable for the desired purpose.

Referring now to Fig. 2 the curve A indicates the current in the grid circuit of the device 1, with varying voltages on the grid. The abscissæ of the curve represent voltage and the ordinates current. It will be noted that over a considerable range of voltage when the grid voltage is negative the cur-

rent in the grid circuit decreases with an increase of the negative grid voltage. That is, at the point B on the current curve which represents a very small negative voltage the current in the grid circuit is greater than at the point C, which represents a much larger negative grid voltage. This characteristic of the current curve is probably due to the effect of slight traces of residual gas in the device and the consequent positive ionization. The greater the negative grid voltage the lower the plate current and therefore the lower the amount of positive ionization in the device due to residual gas therein. As a result, therefore, the grid current will decrease by reason of the smaller number of positive ions which may reach the grid.

If the battery 7 is of such potential that the grid current will fall upon some portion of the current curve between the points B and C, oscillations will be produced in the grid circuit. The frequency of the oscillations produced may be readily varied by adjusting the condenser 6. Inductances 8 and 9 should be employed in series with battery 7 of such value that there will be no damping of the oscillating circuit due to the connection of the battery 7 across the circuit. With the device producing oscillations of the desired frequency oscillations received upon the antenna 10 may be impressed upon the inductance 5 by means of the coupling coil 11 which is included in the antenna circuit. The received oscillations will combine in the grid circuit with the locally produced oscillations in the well-known manner and produce beats. In other words, the potential of the grid 4 will oscillate and the amplitude of the oscillations will vary at a frequency corresponding with the beat frequency produced. As a result a beat current will be produced in the plate circuit of the device, energy for which is supplied by the direct current generator 12, and the beats in the plate current may be detected by the usual telephone receiver 13. The telephone receiver 13 may, if desired, be shunted by a capacity 14 for by-passing the radio frequency component of the current in the plate circuit.

I have found that in most cases fairly high potentials must be employed in the plate circuit in order to secure the desired operation. For example, with one particular device I have found that a plate potential of about 375 volts was necessary in order to secure the desired operating characteristic.

While I have illustrated only one circuit connection whereby oscillations may be produced, and have indicated but one use for the oscillations, it will be apparent that many modifications in the circuit connection employed as well as in the use to which the oscillations are applied may be made without departing from the scope of my invention as set forth in the appended claims.

What I claim as new and desire to secure by Letters Patent of the United States, is:—

1. Means for producing high frequency oscillations comprising an electron discharge device having an electron emitting cathode, an anode and a discharge controlling grid inclosed in an evacuated receptacle, a plate circuit which includes the cathode and anode of said device and a source of potential, a resonant grid circuit which includes the cathode and grid of said device, said device and its associated circuits being so constructed and adjusted that the current in the grid circuit will vary inversely as the applied potential over a given operating range of negative potential and a source of potential connected to the grid circuit of such value that the normal potential of the grid is within said operating range, whereby oscillations will be produced in said grid circuit independently of any coupling between grid and plate circuits.

2. Means for producing high frequency oscillations comprising an electron discharge device having a plate circuit and a resonant grid circuit, said device and its associated circuits being so constructed and adjusted that the current in the grid circuit will vary inversely as the applied potential over a given operating range of negative potential and a source of potential connected to the grid circuit of such value that the normal potential of the grid is within said operating range, whereby oscillations will be produced in said grid circuit independently of any coupling between grid and plate circuits.

3. The combination in a radio receiving system of an electron discharge device having a plate circuit and a grid circuit which is resonant to a frequency differing by an amount within the range of audibility from the waves to be received, means for impressing received waves upon said grid circuit, said device and its associated circuits being so constructed and adjusted that the current in the grid circuit will vary inversely as the applied potential over a given operating range of negative potential, a source of potential connected to the grid circuit of such value that the normal potential of the grid is within said operating range whereby oscillations will be produced in said grid circuit independently of any coupling between grid and plate circuits which will combine with the received oscillations to produce beats and means for detecting the beats thus produced.

4. The combination in a radio receiving system of an electron discharge device having a plate circuit and a grid circuit which is

resonant to a different frequency from that of the waves to be received, means for impressing received waves upon said grid circuit, said device and its associated circuits being so constructed and adjusted that the current in the grid circuit will vary inversely as the applied potential over a given operating range of negative potential, a source of potential connected to the grid circuit of such value that the normal potential of the grid is within said operating range whereby oscillations will be produced in said grid circuit independently of any coupling between grid and plate circuits which will combine with the received oscillations to produce beats and means for detecting the beats thus produced.

5. The combination in a radio receiving system of an electron discharge device having a plate circuit and a grid circuit which is resonant to a frequency differing by an amount within the range of audibility from the waves to be received, means for impressing received waves upon said grid circuit, said device and its associated circuits being so constructed and adjusted that the current in the grid circuit will vary inversely as the applied potential over a given operating range of negative potential, a source of potential connected to the grid circuit of such value that the normal potential of the grid is within said operating range whereby oscillations will be produced in said grid circuit independently of any coupling between plate and grid circuit which will combine with the received oscillations to produce beats and means in the plate circuit of the device for detecting the beats thus produced.

6. The method of operating an electron discharge device having an electron emitting cathode, an anode and a discharge controlling grid inclosed in an evacuated receptacle and having a plate circuit and a resonant grid circuit associated therewith which consists in generating high frequency oscillations in said grid circuit independently of any transfer of energy to said grid circuit from other circuits.

7. The method of receiving signals in a receiving system comprising an electron emitting cathode, an anode and discharge controlling grid inclosed in an evacuated receptacle and having a plate circuit and a resonant grid circuit associated therewith which consists in impressing received signaling currents upon said grid circuit, generating oscillations in said grid circuit of a frequency differing from that of the signaling currents independently of any transfer of energy to said grid circuit and thereby producing a beat current in said grid circuit and amplifying and detecting the beats thus produced.

8. The method of operating a signal receiving system comprising an electron emitting cathode, an anode and a discharge controlling grid inclosed in an evacuated receptacle and having a plate circuit and a resonant grid circuit containing a source of energy associated therewith which consists in generating high frequency oscillations in said grid circuit independently of any transfer of energy to said grid circuit from other circuits, and producing by the conjoint action of the locally generated oscillations and received oscillations an audio frequency current in the plate circuit.

In witness whereof, I have hereunto set my hand this 1st day of June, 1918.

WILLIAM C. WHITE.

Claimant's Exhibit No. 262

the behavior of the dynatron in any circuit containing resistance, capacity, inductance and electromotive force can be accurately calculated by treating the dynatron as a linear conductor with negative resistance r. Examples of such calculations are given below.

The term i_0 in the above equation disappears if the dynatron is connected in series with a battery, of voltage equal to that at which the dynatron current is zero (point B, Figure 3). The combination is a *true* negative resistance, for which $i = \frac{E}{r}$. For example, if the dynatron of Figure 1 be put, with its batteries, in a box, and two wires be brought out thru the box as terminals,

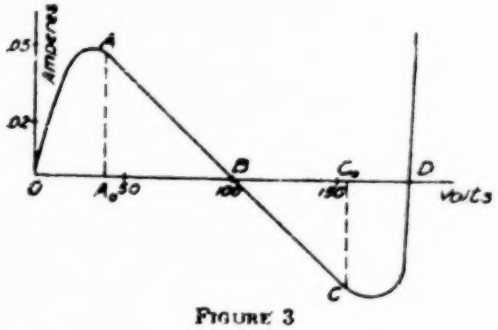

FIGURE 3

one from the plate P and one from a point V_0 of the battery corresponding to the point B of Figure 3, this "negative resistance box" would behave in all respects like a conductor with negative resistance, over the range of voltage, positive and negative, represented by BC_0 and BA_0 in Figure 3.

The magnitude of the negative resistance, which is the slope of the current voltage curve, Figure 3, and the range of voltage $A_0 - C_0$ over which it can be used, depends upon the anode voltage, the temperature of the filament, and, to some extent, on the shape and material of the electrodes. The effect of varying anode voltage alone is shown for two different types of tube in Figures 4 and 5, and the effect of varying filament temperature in Figure 6. It is seen that the effect of varying anode voltage is, in general, to shorten or lengthen the range of the negative resistance part of the curve, without changing the value of the negative resistance. A slight shift in the voltage V_0 at which the curves cross the axis is, for one tube, to the right with increasing voltage, and for the other, to the left. It is

Claimant's Exhibit No. 263

varied by varying any of the applied voltages. Another condition for equation (4) is that the grid should not become sufficiently positive to distort the characteristic. Under these conditions I have generally found this equation to hold sufficiently well, to a first approximation at least, and have been using it in connection with work on the amplifier tube. The above equation does, however, not hold sufficiently accurately for purposes of radiodetection, since this is determined by second order quantities.

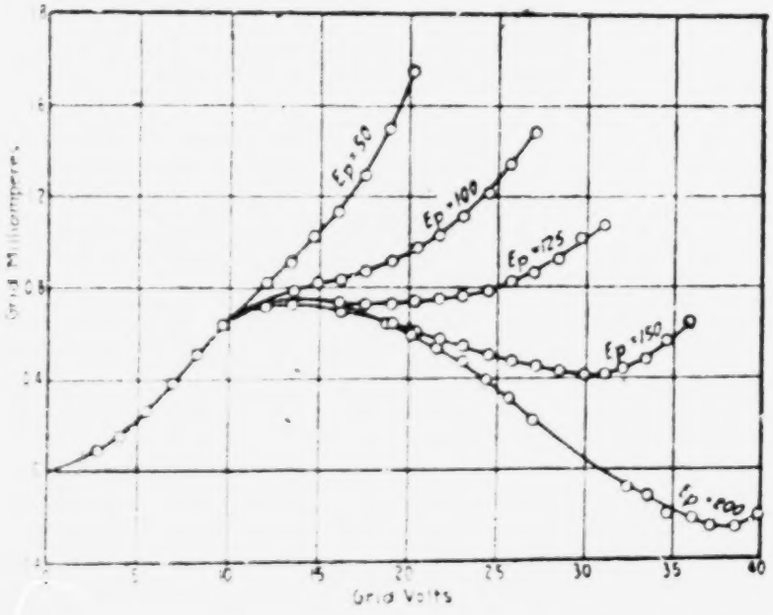

FIG. 78.

Latour[1] has derived some equations for the "relay effect" of audion tubes. He starts from the general functional expressions for the plate and grid currents: $I_p = F(E_p, E_g)$ and $I_g = f(E_g, E_p)$. In the expansion of these equations he neglects all quantities of the second and higher order, thus assuming that the current and voltage variations are very small, or that the characteristic is linear over the operating range.

[1] M. Latour, Electrician, December, 1916.

2700

PLAINTIFF'S EXHIBIT 264

the internal resistance of the battery B, but not the internal plate resistance R of the tube. The grid G is connected to the filament through a battery C which determines the operating point of the tube on the static characteristic curve, and through an alternator D which impresses between the grid and the filament the emf. to be amplified.

In order to facilitate reference, the following letter symbols used are tabulated.

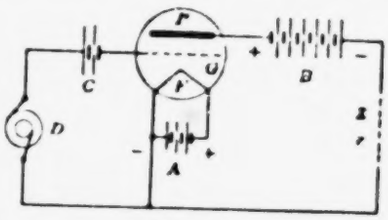

FIG. 145.

R = internal plate resistance of the tube.

E_g = instantaneous difference of potential between grid and filament.

E_p = instantaneous difference of potential between plate and filament.

e_g = instantaneous alternating grid emf.

E_b = plate battery emf.

E_c = grid battery emf.

I_p = instantaneous total current in the plate circuit.

I_p = direct current component of the plate current.

i_p = alternating current component of the plate current.

Z = impedance of the external plate circuit.

r = resistance of the external plate circuit.

k = amplification factor of the tube.

It was seen in Chapter VI that the current in the plate circuit for various values of plate and grid emf's., as represented by the static characteristic of the tube, may be expressed by the relation

$$I_p = a(E_p + kE_g)^m$$

where m was seen to be equal to 2 or $3/2$. If however only the straight central portion of the characteristic curve is considered, as is generally the case for amplification, or if the operation extends only over a small part of the curve, then m may be made equal to unity, and the equation becomes

$$I_p = a(E_p + kE_g) \tag{25}$$

and the internal plate resistance of the tube is

$$R = \frac{E_p + kE_g}{I_p}, \tag{26}$$

e_g produces synchronous variations of the plate current along the static characteristic curve of the tube corresponding to the plate voltage E_b. Thus, if the tube is operating at a plate potential of 200 volts, its characteristic curve will be the curve of Fig. 146 for a plate potential of 200 volts, and if the grid emf. is varied between -20 and $+20$ volts, the plate current will vary along the curve "200," from 3 to 67 milliamperes.

Suppose now, Fig. 145, that the plate circuit contains a resistance r. That is, to simplify the problem, suppose that the impedance Z of the external plate circuit is a resistance of value

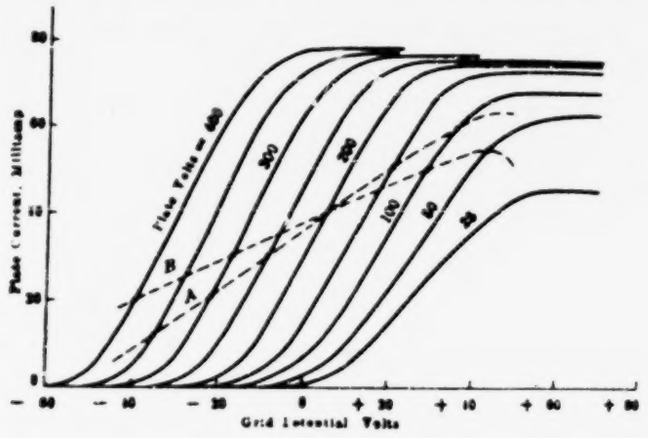

FIG. 146.

r. The emf. E_b of the battery B is then equal to the potential drop rI_p along the resistance r plus that, $I_pR = E_p$, between the filament F and the plate P of the tube, I_p being the current flowing in the plate circuit. Thus,

$$E_b = E_p + rI_p$$

from which

$$E_p = E_b - rI_p \tag{30}$$

which expresses the difference of potential between the plate and filament of the tube.

If now the grid potential E_g is varied so as to increase the current I_p in the plate circuit, it is seen that the resistance drop rI_p in the external plate circuit will correspondingly increase. It then follows from equation (30) that, with the battery voltage E_b remaining constant, *the plate potential* E_p *will de-*

3118

creases. Conversely, if the current I_p is decreased by decreasing the grid potential, the plate potential E_p will increase. Thus, on account of the external resistance of the plate circuit, the plate potential is no longer constant, but is a function of the plate current, and varies in opposite direction to the latter. In other words, the tube, operated under such conditions, has a *negative plate resistance reaction* as defined in connection with the oscillating arc, Chapter V. This will be taken up in greater detail in a later paragraph.

It follows from the above discussion, that when the external plate circuit has resistance and the grid potential is varied, the operating point of the tube no longer follows the static characteristic curve of the tube, which corresponds to a constant value of plate potential, but follows a different curve, called the *dynamic characteristic*. The shape of this characteristic curve depends on that of the static characteristic of the tube (and therefore on the tube construction and constants) and also on the resistance or impedance of the external plate circuit. This is shown in Fig. 146. The solid line curves are the static characteristic curves of the tube, while the dotted lines A and B represent the dynamic characteristics of the tube having an external plate circuit resistance of 5000 and 10,000 ohms, respectively. Thus, with an alternating grid potential and no resistance in the plate circuit, the tube follows the static characteristic curve corresponding to the potential E_b of the battery B. With an external plate circuit resistance of 5000 ohms, the operating point follows curve A, and with a resistance of 10,000 ohms, it follows curve B. Each of the curves A and B corresponds to a certain value of plate battery voltage. If this is changed, then the dynamic characteristic curve for a given external plate impedance will be shifted accordingly.

As expressed by the last equation, the greater the resistance r of the external plate circuit, or, more generally, the greater its impedance Z, the greater the variation of plate potential E_p resulting from a given change of plate current I_p brought about by a given variation of grid potential. This is shown in the curves of Fig. 146, where it may be seen that the slope of the dynamic characteristic curve decreases as the resistance (or impedance) of the external plate circuit is increased. As an extreme case, for infinite impedance, the curve would be parallel to the grid voltage axis of Fig. 146, showing that variations of grid

UNITED STATES PATENT OFFICE.

REGINALD A. FESSENDEN, OF PITTSBURG, PENNSYLVANIA.

RECEIVER FOR ELECTROMAGNETIC WAVES.

SPECIFICATION forming part of Letters Patent No. 727,331, dated May 5, 1903.

Application filed [illegible], 1903. Serial No. 151,617. (No model.)

To all whom it may concern:

Be it known that I, REGINALD A. FESSENDEN, a citizen of the United States, residing at Pittsburg, in the county of Allegheny and State of Pennsylvania, have invented or discovered certain new and useful Improvements in Receivers for Electromagnetic Waves, of which improvements the following is a specification.

The invention described herein relates to certain improvements in current-actuated wave-responsive devices of the class or kind described and claimed in Letters Patent No. [illegible], granted to me August 12, 1902, and which may be so affected by currents generated by electromagnetic waves as to produce a material variation of the conductivity of the receiving-circuit, of which said device forms a part.

The invention is hereinafter more fully described and claimed.

In the accompanying drawings, forming a part of this specification, Figure 1 is a sectional view of a form of receiver embodying my invention. Figs. 2, 3, 4, and 5 are sectional views of modified forms of receiver. Fig. 6 is a diagrammatic view illustrating the operation of the receiver. Fig. 7 is a detail illustrating further modifications in the construction of the receiver.

In the use of the hot-wire receiver described in the above-cited patent referred to, and which is sometimes termed a "barretter," that portion of the electromagnetic waves is utilized which heats a body of small mass, and which thereby causes a small amount of energy to produce such an extent as to change its conductivity. Heretofore metals, such as platinum and silver, have been employed, as described in the patent referred to; but I have found that in instances other substances are available for this purpose, as, for example, liquids, and of the latter class electrolytes have given even better general results than metals, for the following reasons: first, for the reason that they are not, by reason of their nature, subject to excessive discharges; second, because the specific resistance of liquids is much greater, in some cases as much as a million times greater, than that of metals, and consequently to obtain the same resistance a very much smaller mass, which is capable of being heated to a much larger extent, may be used; third, because the amount of change of resistance per degree of centigrade is very much greater—for example, the resistance of sulfuric acid when not quite concentrated changes approximately twelve per cent. per degree centigrade, while the change in platinum is only about one-third of one per cent. per degree centigrade. For all these reasons the results produced are very much greater and the action of the receiving device is much more reliable.

A liquid barretter or current-actuated wave-responsive device may be constructed in several ways. For instance, it is found that if the loop of a metal barretter such as described in the patent be broken while it is immersed in nitric acid it will nevertheless act even more efficiently than before, and hence a barretter may be formed consisting of two thin platinum wires 2 and 3, as shown in Fig. 1, having their ends immersed in a liquid contained in a suitable vessel 4 and forming, together with such liquid, a part of a receiving-circuit, including an indicating device 5. This barretter may be connected either directly or indirectly with a receiving-vertical 1. A second method is to moisten a minute fiber—for example, a cotton thread—and to use it as the loop of a barretter. A desirable construction for this form of barretter is shown in Fig. 2 and consists of a fiber loop 6, having one end immersed in a liquid, which will be caused to travel along the fiber by capillary action and maintain the fiber in a saturated condition. A third method consists in forming a minute hole through a diaphragm 7, conveniently done by drawing down a very thin capillary tube to about three one-thousandths (.003) of an inch internal diameter, cementing it into a hole in the center of a thick glass disk, and then grinding off the ends of the glass tube until they are flush with the surface of the diaphragm. The diaphragm is so arranged in a suitable vessel 4 as to form a partition between two portions of the solution in the cup or holder shown in Fig. 3, said portions being thus separated except by the thin column of the liquid contained in the capillary tube, said column forming the barretter. A ter-

3122

minal 9, preferably of platinum, connected to the vertical, is immersed in one portion of the liquid, and a second terminal 10, preferably of platinum also, is connected to ground and has one end immersed in the other portion of the liquid. These platinum wires, with the liquid, are to be connected either directly in series with the vertical or in the secondary of a transformer, and the barretter thus formed is adapted to be used in the manner described in prior patents granted to me. A fourth method is to connect two platinum wires by a thin film or small body of conducting liquid, as indicated in Fig. 4. This can be done conveniently by inserting the wires into a bubble 11, formed of such liquid. A fifth method is to insert a small piece 12, of platinum or similar material, into a liquid, such as nitric acid, so that only its point is immersed. Fig. 5 shows such an arrangement, the platinum wire being covered with silver. The silver wire has a diameter of about .003 of an inch, and the platinum core inclosed therein has a diameter of about .00004 of an inch. The silver is removed or eaten off from the lower extremity, and the platinum core projects into the solution of nitric acid. This solution of nitric acid, which preferably contains nitrous acid, is covered by a layer of kerosene-oil, so as to prevent evaporation of the acid and to prevent the platinum from being fused. A second platinum wire 13 is also immersed in the liquid, preferably by inserting it through the bottom of the vessel 4, and these wires are connected to the vertical and to ground and also included in the indicating-circuit. It follows from the well-known electrical formula giving the resistance of a cylindrical body in a conducting medium that practically all the resistance is concentrated within a short distance of the point where the platinum wire 12 projects into the acid. For example, if the platinum has a diameter of .00004 of an inch, and it is immersed in the acid to a depth of .00002 of an inch, practically all the temperature effected will take place inside of a hemisphere of liquid whose radius is .00004 of an inch. Such a hemisphere is indicated in Fig. 6, where 2 represents the tip of the platinum, and represents the hemisphere referred to. That this is true will be seen by considering a second hemispheric shell 14, having the thickness of .00004 of an inch outside of the hemisphere 15. The quantity of liquid in this shell 14 will be more than eight times that in the shell 15, and consequently it will take eight times the amount of heat to raise it to this same extent. At the same time the resistance of the shell 14 will be roughly the same as that of 15. Hence it follows that the effect of the shell 14 will be only one eighth that of 15, and consequently that although the effect of the different parts of the liquid within the boundary of 15 does not vary much and all parts are almost equally efficient, as soon as we pass the boundary of 15 the effect of the variations of liquid beyond the boundary begins to fall off very rapidly, and at a distance of two or three times the diameter of the wire it may be neglected. This may be deduced at once from the proposition that the electrical resistance between two copper disks laid on a plate of sheet-copper is conditioned almost entirely by the size of the disk, and by the conductivity of the copper sheet; while it is not affected except to an unappreciable extent by the distance between them. As shown in Fig. 7, the terminal 12 may be inserted through the bottom of the vessel 4, in which case an indicating liquid, such as bisulfid of carbon, having a greater specific gravity than the nitric acid is used in connection with the latter. As indicated in Fig. 8, the wire 12 may be surrounded with glass, so as to prevent any gas given off from adhering to the wire, and thereby decreasing its effective area.

The arrangement of circuits used with the liquid barretter is practically the same as that with the metal barretter described in the patent referred to.

It is found that certain liquids act better than others—as, for example, though carbonate of soda, caustic soda, nitrate of potash, and other substances give good results, it is preferred to use nitric acid, for the reason that the effects are stronger with it than with most other liquids, and in the case of a burn-out it is sufficient to screw down the platinum wire until it is again immersed. The burn-out is not liable to occur, on account of the cooling effect of the liquid on the wire. When using silver-coated platinum wire, the screwing down of the wire into the nitric acid will subject the silver to the action of the acid, which will remove it from the platinum. If, however, a high voltage—*e. g.*, seven or eight—be used in the local circuit, carbonate of soda will give larger effect than nitric acid.

It is to be noted that in the case of the liquid barretter the action of the electromagnetic waves is to cause a greater current to pass in the local circuit, owing to the fact that the conductivity of electrolytes increases instead of decreases with heat. With a liquid barretter having a resistance of between six hundred and two thousand ohms the increase of conductivity when the liquid is heated is so marked as to permit of the operation of a siphon recorder or relay, though a telephone may be used.

It is to be noted that there are several distinct methods in which metal and liquid can be used in conjunction to form a receiver for electromagnetic waves. First, the case of a conductor, such as oxidized silver, in contact with a liquid like mercury, where the action is apparently a true coherer action caused by the voltage produced by the electromagnetic waves breaking down the insulating-oxid and making a good electrical contact between the silver and mercury. This effect does not oc-

is not utilized in my form of liquid barretter, for, in the first place, the resistance of the apparatus, if constant and definite, does not alter by shock or jar, returns to the same value no matter what the strength of the wave, and an entirely new piece of wire immersed to the same depth when a burnout has occurred allows the same current to pass as any other similar piece of wire. Again, the increase of conductivity is always the same in amount under the same conditions and is exactly what calculations show should be produced by the heating of the liquid. Secondly, the change of resistance is exactly proportional to the energy of the electromagnetic waves, thus differing from the operation of the coherer. Third, if the size of the platinum wire be increased, the effect falls off very rapidly, as it should do according to theory, while in the case of coherer this is not true.

A second method of using liquid and metal is illustrated in Fig. 3 of Letters Patent No. 706,748, dated August 12, 1902, for rectifying the alternating currents produced by the electromagnetic waves. This effect does not occur when using my improved form of receiver, as may be readily shown by substituting such receiver for the electrolytic cell shown in the patent, in which case no such rectification will be found to occur. The evident reason for this is the fact that the resistance of the liquid barretter is so arranged as to absorb the energy and not to allow any of it to pass through. The energy by being absorbed none of it can be rectified. A second reason is that the polarization capacity of the barretter is too small to permit of such rectification. A third proof of this consists in the fact that the signals are obtained almost as well when both terminals consist of similar pieces of platinum, in which case, according to theory, there should be no rectification.

A third method consists in utilizing the depolarization of the electrode caused by the heating of the liquid. While there is no doubt that such an effect is probably produced, it is masked, and when in actual working practically the entire effect seems to be due to the change in resistance. An effect which appears when the voltage of the local circuit is raised to such a point as to cause the gases to bubble off from the point gives rise to a fourth method. When this is the case, the waves effect an increase in resistance instead of diminution, possibly by first causing the bubble of gas to be deposited, which decreases the area of contact between the liquid and the platinum wire. This action is, however, irregular and occurs only at a certain critical point, and as it does not always occur and regularly it is not available for actuating an indicating mechanism.

While the liquid receiver will work well no matter which pole is connected to the platinum, it is found in practice that better results are obtained when the platinum point is made negative, probably because bubbles of gas which may come off are dissolved in the liquid and tend to maintain the conductivity.

I claim herein as my invention—

1. A receiver for electromagnetic waves having a small heat capacity and consisting of a small quantity of liquid, substantially as set forth.

2. A receiver for electromagnetic waves consisting of a small quantity of liquid, the conductivity of which is affected by the action of electromagnetic waves, substantially as set forth.

3. A receiver for electromagnetic waves consisting of a small quantity of liquid adapted to have its resistance decreased by the action of electromagnetic waves, substantially as set forth.

4. A receiver for electromagnetic waves consisting of a material increasable in conductivity by currents produced by electromagnetic waves, substantially as set forth.

5. A receiver for electromagnetic waves consisting of a liquid and rapidly responsive as regards temperature to effects produced by electromagnetic waves, substantially as set forth.

6. A receiver for electromagnetic waves consisting of a small quantity of nitric acid, substantially as set forth.

7. A receiver for electromagnetic waves, having in combination a small quantity of nitric acid, and terminals formed of platinum immersed in said liquid, substantially as set forth.

8. A receiver for electromagnetic waves having all its contacts perfect contacts and formed of a material increasable in conductivity by currents produced by electromagnetic waves, substantially as set forth.

9. A receiver for electromagnetic waves, having in combination a small quantity of nitric acid, and terminals formed of platinum immersed in said liquid, the positive terminal having an external covering, substantially as set forth.

In testimony whereof I have hereunto set my hand.

FREDERICK K. VREELAND, OF MONTCLAIR, NEW JERSEY, ASSIGNOR TO WIRELESS TELEGRAPH EXPLOITATION COMPANY, OF NEW YORK, N. Y., A CORPORATION OF NEW YORK.

METHOD OF RECEIVING ELECTROMAGNETIC WAVES OR OTHER FEEBLE SIGNAL IMPULSES.

SPECIFICATION forming part of Letters Patent No. 780,842, dated January 24, 1905.

Application filed August 1, 1904. Serial No. 219,013.

To all whom it may concern:

Be it known that I, FREDERICK K. VREELAND, a citizen of the United States, residing at Montclair, in the county of Essex and State of New Jersey, have invented a certain new and useful Method of Receiving Electromagnetic Waves or other Feeble Signal Impulses, of which the following is a description.

The object I have in view is the production of a method for the detection of electromagnetic waves or other feeble electrical signal impulses.

The invention has been found especially useful for the reception of signals in wireless telegraphy.

My invention depends upon the discovery made by me that an electrolytic cell of a special character when polarized to the proper critical point by a local battery is extremely sensitive to transitory or rapidly-oscillating currents from another source which when passed through it tend to depolarize the cell and cause it to offer less opposition to the passage of the local current, which rises and falls in value with the presence and absence of the transitory waves or impulses and affords an effective means for operating a telephone or other signal receiver. The polarized cell is one of special character, particularly in the respect that the anode of the cell (i. e., the electrode connected with the positive pole of the local battery) presents to the electrolyte a minute surface, producing a cell of minute electrolytic capacity. This I have found enables the cell to be depolarized sufficiently by electromagnetic waves or other feeble signal impulses to cause variations of the local current therethrough great enough effectively operate a telephone or other signal receiver. The anode of the cell may be made of any suitable metal or other conducting material which is not changed by the electrolyte or attacked by the gaseous ions which are produced thereat. It may consist of a minute platinum wire having a diameter approximately .0001 inch and immersed in the electrolyte a few thousandths of an inch or the diameter may be .0005 of an inch, as it may be, the surface presented to the electrolyte is approximately .001 square millimeter. The size of this minute surface may be varied considerably in the region of this value. To obtain the best results, the area of contact-surface between the anode and the electrolyte should be properly proportioned to the intensity of the impulses to be detected. In general the apparatus becomes more sensitive to feeble impulses as the size of the anode is diminished; but when stronger impulses are received an increased effect may be obtained in the receiving instrument by increasing the area of the anode. For a given strength of impulse there is usually a certain size of anode which gives the maximum effect. If the anode be made larger than this, the apparatus becomes less sensitive. If it be made smaller, the strength of the impulse is more than sufficient to effect the depolarization of the cell and the remaining energy is wasted. In practice, however, an anode small enough to be sensitive to the most feeble impulses to be received will usually work well with any stronger impulse. I have found that a platinum wire of .0001 inch in diameter immersed in the electrolyte a few thousandths of an inch will meet this practical condition. This minute wire may be produced by drawing down a large silver wire with a platinum core, after which the end of the platinum core is exposed by dissolving the silver in nitric acid. As the useful action of polarization occurs at the anode, the size of the cathode is of little importance, though it should be preferably much larger than the anode. I use ordinarily a cathode of platinum wire .01 inch in diameter sealed into the bottom of a small glass vessel and projecting into the electrolyte one-quarter of an inch. If the cathode be made as small as the anode, the device will still operate, but less efficiently owing to the increased resistance of the cell. The distance between the anode and the cathode is also immaterial except as it affects the resistance of the cell. Ordinarily I prefer to place them about one-half inch apart, though this distance may be decreased to a few thousandths of an inch or increased to several inches without greatly affecting the result.

creases under the influence of the oscillations from .000003 to .000009 of an ampere. These are the steady values of the current. The momentary increase while the cell is readjusting itself to the changed conditions is very much greater and being of a sudden and transitory character has a much larger effect upon a telephone connected in the circuit than would be indicated by the values derived from the curve. For these reasons the apparatus is most sensitive when used with a telephone for receiving audible signals; but the constant increase of current indicated by the curve may also be utilized to operate a siphon-recorder or other recording apparatus. The terminal voltage of the cell produced by the local battery at which the cell is most sensitive to electromagnetic waves or other feeble impulses varies with different electrolytes and with different strengths of the solution. The cell is sensitive to oscillations over a considerable range of electromotive force; but it works most efficiently at a point a little below the bend of the curve, where a decided evolution of gas begins to occur. At this point the cell is less stable than at other voltages, and any stimulus gives a greater change in the state of polarization, and hence in the local current. This best voltage is about 1.8 volts for strong nitric acid, is higher for dilute acid, and may reach four or five volts or more in dilute caustic-kali solutions. Where the feeble impulses to be detected are unidirectional, care should be taken that they are passed through the cell in a direction opposite to the flow of the current from the local battery. These impulses will then have the effect of momentarily diminishing or even entirely annulling the existing polarization, resulting in the flow of a largely-increased current from the local battery through the depolarized cell. The apparatus is thus useful for detecting the feeble and transitory currents employed in cable telegraphy or for similar uses. If the polarity of the local battery is reversed—*i. e.*, its negative pole is connected to the electrode of minute surface—the apparatus becomes inoperative for the detection of electromagnetic waves or other feeble signal impulses. In this case the large terminal becomes the anode and the currents to be detected are too feeble to effect any appreciable change of polarization over its large surface. The apparatus will work with a voltage of the local battery considerably below the decomposition voltage of the cell, especially when the impulses to be detected are strong; but under these conditions the apparatus is less sensitive. I prefer, however, to produce by the local battery a difference of potential at the terminals of the cell somewhat higher than the decomposition voltage of the cell, but below the point where violent evolution of gas is caused.

My detector of electromagnetic waves, the method of operation of which and those principal constructional features have already been described, possesses numerous advantages over apparatus heretofore employed for the same purpose. It is extremely sensitive and responds to the most rapid impulses, being practically instantaneous in action. It is reliable and permanent in adjustment, does not require delicate handling or adjustment in operation, is not injured by lightning discharges or by the transmitting apparatus, lends itself readily to tuning—*i. e.*, selective signaling—is capable of being used either for the production of audible signals by a telephone or for the recording of signals, and, finally, it is characterized by extreme simplicity of construction.

In the drawings, Figure 1 is a top view of the cell-support and its constructional adjuncts. Fig. 2 is a vertical section of the apparatus of Fig. 1, the size of the minute anode being necessarily exaggerated. Fig. 3 is an enlarged view of the cell. Fig. 4 is a diagram illustrating the connections of the cell for receiving electromagnetic waves, and Fig. 5 represents curves illustrating the action of the cell.

The cell C is a small glass vessel containing the electrolyte 1, into which dips the minute anode 2. The cathode 3 of larger area is sealed into the glass bottom of the vessel C, projecting inwardly into the electrolyte and outwardly beyond the bottom of the vessel. The cell C is removably mounted in a socket 4, terminating in a mercury-cup 5, into which the outer end of the cathode 3 projects for making connection with the cathode. A bushing 6, of soft-rubber tubing, is inserted in the socket 4 to make a tight fit with the glass cell, so as to hold it firmly in place and prevent spilling of the mercury. The socket 4 is mounted upon a base 7, both the socket and base being preferably of a material not affected by the electrolyte. The minute anode 2 is supported by a silver jacket 8, which is attached to a copper wire 9, held by a screw-clip 10 on the end of a horizontal arm 11. This arm is mounted upon a standard 12 on the base 7 by a long sleeve 13. Springs 14, attached to the arm 11, bear against the flat face of the standard 12, so as to take up lost motion. The arm 11 is guided in its movement on the standard 12 by a pin 15, working in slots 16, the upper ends of these vertical slots 16 being extended into lateral slots 17, so as to permit the arm 11 to be swung to one side when moved to its uppermost position and after the anode is clear of the cell. The standard 12 is hollow, and within it is placed a spiral spring 18, pressing downwardly on the cross-pin 15 and surrounding a screw 19, which extends upwardly from the cross-pin through a cap 20 on the top of the standard 12. The cap 20 confines the spring 18, which spring exerts a downward pressure on the cross-pin 15, tending to keep the arm

H in its lowermost position. The arm H is lifted by means of a nut 21 turning upon the screw 19 and bearing upon the cap 20. The top of the nut 21 may be graduated to show the degree of adjustment. Binding-posts 22 are connected with the mercury-cup 5 and through it with the cathode of the cell, while binding-posts 23 are connected with the standard 12 and through it with the anode of the cell.

Referring to Fig. 4, which shows the connections of the apparatus for use as a receiver in wireless telegraphy, 24 is the local battery, having its positive pole connected to the anode of the cell and its negative pole connected to the cathode. 25 is an adjustable resistance-coil or potentiometer connected in shunt to the battery and cell, whose function is to regulate the voltage across the terminals of the cell. This coil is wound inductively to prevent the escape of the oscillations through itself or through the battery, a sufficient length of the coil for this purpose being always maintained in circuit between the battery and the cell. 26 is a telephone-receiver which is connected in the battery-circuit between the potentiometer and the cell. 27 is the antenna or aerial wire, and 28 is the ground-wire, which are connected, respectively, with the anode and cathode of the cell, but may have reverse connections with the cell.

The operation of the apparatus is evident from the description already given.

The apparatus described is not claimed herein, but will be made the subject of a divisional application.

What I claim is

1. The method of detecting electromagnetic waves or other feeble electrical impulses, which consists in polarizing an electrolytic cell of minute electrolytic capacity, effecting by such waves or impulses a partial or complete depolarization of such cell, and observing increases in current caused by the depolarization of the cell by said waves or impulses.

2. The method of detecting electromagnetic waves or other feeble electrical impulses, which consists in polarizing an electrolytic cell having a minute anode, effecting by such waves or impulses a partial or complete depolarization of such cell, and observing increases in current caused by the depolarization of the cell by said waves or impulses.

3. The method of detecting electromagnetic waves or other feeble electrical impulses, which consists in polarizing an electrolytic cell having a minute anode at which gas is evolved, effecting by such waves or impulses a partial or complete depolarization of such cell, and observing increases in current caused by the depolarization of the cell by said waves or impulses.

4. The method of detecting electromagnetic waves or other feeble electrical impulses, which consists in polarizing an electrolytic cell having a minute anode at which oxygen is evolved, effecting by such waves or impulses a partial or complete depolarization of such cell, and observing increases in current caused by the depolarization of the cell by said waves or impulses.

5. The method of detecting electromagnetic waves or other feeble electrical impulses, which consists in polarizing, by a local source of electromotive force, an electrolytic cell, passing the waves or impulses to be detected through said cell in such manner as to wholly or partially depolarize the cell and thereby increase the current in the local circuit, and observing the variations in flow of the local current.

6. The method of detecting electromagnetic waves or other feeble electrical impulses, which consists in polarizing, by a local source of electromotive force, an electrolytic cell having a minute anode, passing the waves or impulses to be detected through said cell in such manner as to wholly or partially depolarize the cell and thereby increase the current in the local circuit, and observing the variations in flow of the local current.

7. The method of detecting electromagnetic waves or other feeble signal impulses, which consists in polarizing by a local source of electromotive force an electrolytic cell, passing the waves or impulses to be detected through said cell in parallel with the polarizing current, and observing the variations in flow of the local current.

8. The method of detecting electromagnetic waves or other feeble signal impulses, which consists in polarizing by a local source of electromotive force an electrolytic cell having a minute anode, passing the waves or impulses to be detected through said cell in parallel with the polarizing current, and observing the variations in flow of the local current.

9. The method of detecting electromagnetic waves or other feeble electrical impulses, which consists in polarizing an electrolytic cell by an impressed voltage higher than the decomposition voltage of the cell but lower than the voltage at which a violent evolution of gas is caused, effecting by such waves or impulses a partial or complete depolarization of such cell, and observing changes in the polarization of the cell caused by said waves or impulses.

10. The method of detecting electromagnetic waves or other feeble electrical impulses, which consists in polarizing an electrolytic cell having a minute anode by an impressed voltage higher than the decomposition voltage of the cell but lower than the voltage at which a violent evolution of gas is caused, effecting by such waves or impulses a partial or complete depolarization of such cell, and observing changes in the polarization of the cell caused by said waves or impulses.

11. The method of detecting electromagnetic waves or other feeble electrical impulses, which

consists in polarizing an electrolytic cell by means of a local source of electromotive force producing at the cell a voltage above the decomposition voltage of the cell but below the point where a violent evolution of gas is caused, passing the waves or impulses to be detected through said cell and thereby wholly or partially depolarizing the same whereby the current in the local circuit will be increased, and observing the variations in flow of the local current.

12. The method of detecting electromagnetic waves or other feeble electrical impulses, which consists in polarizing an electrolytic cell having a single anode by means of a local source of electromotive force producing at the cell a voltage above the decomposition voltage of the cell but below the point where a violent evolution of gas is caused, passing the waves or impulses to be detected through said cell and thereby wholly or partially depolarizing the same whereby the current in the local circuit will be increased, and observing the variations in flow of the local current.

This specification signed and witnessed this 28th day of July, 1904.

Corrections in Letters Patent No. 780,842.

It is hereby certified that in Letters Patent No. 780,842, granted January 24, 1905, upon the application of Frederick K. Vreeland, of Montclair, New Jersey, for an improvement in "Methods of Receiving Electromagnetic Waves or other Feeble Signal Impulses," errors appear in the printed specification requiring correction, as follows: In line 25, page 2, the word "disposition" should read *deposition*; and in line 54, same page, the comma after the word "liquids" should be stricken out; and that the said Letters Patent should be read with these corrections therein that the same may conform to the record of the case in the Patent Office.

Signed and sealed this 7th day of March, A. D., 1905.

[SEAL.]

E. L. ALLEN,
Commissioner of Patents.

[fol. 2716] PLAINTIFF'S EXHIBIT 268

II. "On Electric Discharge between Electrodes at different Temperatures in Air and in High Vacua." By J. A. Fleming, M. A., D.Sc., Professor of Electrical Engineering in University College, London. Communicated by Professor G. C. Foster, F.R.S. Received December 16, 1889.

(Preliminary Notice)

It has been known for some time that if a platinum plate or wire is sealed through the glass bulb of an ordinary carbon filament incandescent lamp, this metallic plate being [fol. 2717] quite out of contact with the carbon conductor, a sensitive galvanometer connected between —s insulated metal plate enclosed in the vacuum and the external *positive* electrode of the lamp indicates a current of some milliampères passing through it when the lamp is set in action, but the same instrument when connected between the *negative* electrode of the lamp and the insulated metal plate indicates no sensible current. This phenomenon in carbon incandescence lamps was first observed by Mr. Edison, in 1884, and further examined by Mr. W. H. Preece, in 1885.*

* See 'Roy. Soc. Proc.,' vol. 38, 1885, p. 219. "On a Peculiar Behaviour of Glow Lamps when raised to High Incandescence."—In this paper Mr. Preece describes a very careful series of observations carried out with Edison incandescence lamps, and which cover the same ground as a portion of the experiments here described. The results given in (4), (7), and (11) confirm the facts which were first ascertained by him. He also arrived at the general conclusion that the phenomena so observed are due to an electric convection by matter projected from the incandescent carbon. By carrying up the working electromotive force of the lamp to a point productive of very high incandescence, he was able to measure the resulting current through a galvanometer connected between the positive lamp electrode and the middle plate corresponding to every degree of incandescence, and showed that, whilst increasing up to a certain point, the galvanometer current fell off rapidly soon after a certain critical temperature was reached, which corresponded to the appearance of a blue light or haze in the glass receiver.—[Jan. 14th, 1890.]

The primary object of the experiments described in this paper was the further examination of this effect, but the inquiry has extended itself beyond this range and embraced some general phenomena of electric discharge between electrodes at unequal temperatures, and in particular has revealed some curious effects in the behaviour of an electric arc taken between carbon poles towards a third insulated carbon or metal poles.

The first series of experiments had reference to the nature of the effect observed in the incandescence lamps having an insulated wire or plate placed in the vacuum.

If a platinum wire is sealed through the glass bulb of an ordinary carbon filament lamp and carries at its extremity a metal plate, so placed as to stand up between the legs of the carbon horseshoe without touching either of them, then when the lamp is actuated by a continuous current it is found that:

(1.) This insulated metal plate is brought down instantly to the potential of the base of the negative leg of the carbon, and no sensible potential difference exists between the insulated metal plate and the negative electrode of the lamps, whether the test be made by a galvanometer, by an electrostatic voltmeter, or by a condenser.

(2.) The potential difference of the plate and the positive electrode of the lamp is exactly the same as the working potential difference of the lamp electrodes, provided this is measured electrostatically, *i.e.*, by a condenser, or by an electrostatic voltmeter taking no current, but if measured [fol. 2718] by a galvanometer the potential difference of the plate and the positive electrodes of the lamp is something less than that of the working lamp electrodes.

(3.) This absolute equality of potential between the negative electrode of the lamp and the insulated plate only exists when the carbon filament is in a state of vivid incandescence, and when the insulated plate is not more than an inch or so from the base of the negative leg. When the lamp is at intermediate stages of incandescence, or the plate is considerably removed from the base of the negative leg, then the plate is not brought down quite to the same potential as the negative electrode.

(4.) A galvanometer connected between the insulated plate and the *positive* electrode of the lamp shows a current

increasing from zero to four or five milliampères, as the carbon is raised to its state of commercial incandescence. There is not any current greater than 0.0001 of a milliampère between the plate and *negative* electrode when the lamp has a good vacuum.

(5.) If the lamp has a bad vacuum this inequality is destroyed, and a sensitive galvanometer shews a current flowing through it when conected between the middle plate and either the positive *or* negative electrode.

(6.) When the lamp is actuated by an *alternating* current a *continuous* current is found flowing through a galvanometer, connected between the insulated plate and *either* terminal of the lamp. The direction of the current through the galvanometer is such as to show that negative electricity is flowing from the plate through the galvanometer to the lamp terminal. This is also the case in (4); but, if the lamp has a bad vacuum, then negative electricity flows *from* the plate through the galvanometer *to* the positive terminal of the lamp, and negative electricity flows *to* the plate through the galvanometer from the negative terminal of the lamp.

(7.) The same effects exist on a reduced scale when the incandescent conductor is a platinum wire instead of carbon filament. The platinum wire has to be brought up very near to its point of fusion, in order to detect the effect, but it is found that a current flows between the positive electrode of a platinum wire lamp and a platinum plate placed in the vacuum near to the negative end of that wire.

(8.) The material of which the plate is made is without influence. Platinum, aluminium, and carbon have been indifferently employed.

(9.) The active agent in producing this effect is the *negative* leg of the carbon. If the negative-leg of the carbon is covered up by enclosing it in a glass tube this procedure entirely, or nearly entirely, prevents the production of a current in a galvanometer connected between the middle plate and the positive terminal of the lamp.

(10.) It is a matter of indifference whether a glass or [fol. 2719] metal tube is employed to cover up the negative leg of the carbon; in any case this shielding destroys the effect.

(11.) If, instead of shielding the negative leg of the carbon, a mica screen is interposed between the negative leg and the side of the middle plate which faces it, then the

current produced in a galvanometer connected between the positive terminal of the lamp and the middle plate is much reduced. Hardly any effect under the same circumstances is produced when the mica screen is interposed on that side of the metal plate which faces the positive leg of the carbon.

(12.) The position of the metal plate has a great influence on the magnitude of the current traversing a galvanometer connected between the metal plate and the positive terminal of the lamp. The current is greatest when the insulated metal plate is as near as possible to the base of the negative leg of the carbon, and greatest of all when it is formed into a cylinder which embraces without touching the base of the negative leg.

The current becomes very small when the insulated metal plate is removed to 4 or 5 inches from the negative leg, and becomes practically zero when the metal plate is at the end of a tube forming part of the bulb, which tube has a bend at right angles in it. Copious experiments have been made with metal plates in all kinds of positions.

(13.) The galvanometer current is greatly influenced by the surface of the metal plate, being greatly reduced when the surface of the plate is made small, or when the plate is set edgeways to the negative leg, so as to present a very small apparent surface when seen from the negative leg. In a lamp having the usual commercial vacuum, the effect is extremely small when the insulated metal plate is placed at a distance of 18 inches from the negative leg, but even then it is just sensible to a very sensitive galvanometer.

(14.) If a charged condenser has one plate connected to the insulated metal plate, and the other plate connected to any point of the circuit of the incandescent filament, this condenser is instantly discharged if the positively charged side of the condenser is connected to the insulated plate, and the negative side to the hot filament. If, however, the negative leg of the carbon horseshoe is shielded by a glass tube, this discharging power is much reduced, or altogether removed.

(15.) If the middle plate consists of a separate carbon loop, which can itself be made incandescent by a separate insulated battery, then, when this middle carbon is rendered incandescent and employed as the metal plate in the above experiment, the condenser is discharged when the nega-

tively charged side of it is connected to the hot middle carbon, the positively charged side of it being in connexion with the principal carbon horseshoe.

[fol. 2720] (16.) If this last form of lamp is employed as in (4) the subsidiary carbon loop being used as a middle plate, and a galvanometer being connected between it and either the positive or negative main terminal of the lamp, then when the subsidiary carbon loop is cold, we get a current through the galvanometer only when it is in connexion with the positive main terminal of the lamp, but when the subsidiary carbon is made incandescent by a separate insulated battery, we get a current through the galvanometer when it is connected either to the positive *or* to the negative terminal of the lamp. In the first case the current through the galvanometer is a negative current, flowing from the middle carbon to the positive main terminal, and in the second case it is a negative current, from the negative main terminal to the middle subsidiary hot carbon.

(17.) If a lamp having a metal middle plate held between the legs of the carbon loop has a galvanometer connected between the negative main terminal of the lamp and this middle plate, we find that when the carbon is incandescent there is no sensible current flowing through the galvanometer. The vacuous space between the middle plate and the hot negative leg of the carbon possesses, however, a curious unilateral conductivity. If a single Clark cell is inserted in series with the galvanometer, we find that this cell can send a current deflecting the galvanometer when its negative pole is in connexion with the negative main terminal of the lamp, but if its positive pole is in connexion with the negative terminal of the lamp, then no current flows. The cell is thus able to force a current through the vacuous space when the direction of the cell is such as to cause negative electricity to flow across the vacuous space from the hot carbon to the cooler metal plate, but not in the reverse direction.

(18.) If a vacuum tube is constructed, having at each end horseshoe carbon filaments sealed into it, and which can each be made separately incandescent by an insulated battery, we find that such a vacuum tube, though requiring an electromotive force of many thousands of volts to force a current through it when the carbon loops are used as elec-

trodes and are *cold*, will yet pass the current from a single Clark cell when the carbon loop which forms the negative electrode is rendered incandescent. It is thus found that a high vacuum terminated electrically by unequally heated carbon electrodes possesses an unilateral conductivity, and that electric discharge takes place freely through it under an electromotive force of a few volts when the *negative* electrode is made highly incandescent.

(19.) These experimental results above described led the writer to investigate, in the same manner, the electric arc between carbon poles taken in air. If an electric arc is formed, in the usual way, between carbon poles, and a third insulated carbon pole is allowed to dip into or touch the electric arc, or, better still, has the electric arc projected against [fol. 2721] it by a magnet, it is found that this third or insulated pole is brought down almost to the potential of the negative carbon of the arc, and that a galvanometer connected between the third insulated carbon and the negative carbon of the arc indicates no current, but that if joined up between the positive carbon and the middle carbon a strong current of about an ampère or so is found to be passing. If an electric bell or an incandescent lamp is joined up between the third carbon and the *negative* carbon of the arc, they do not work; but if the bell or the lamp is joined between the *positive* carbon of the arc and the third carbon, they are set in action by a strong current passing through them. These effects are produced, although the third carbon (which is best held at right angles to the other two forming the arc) is half or three-quarters of an inch away from the positive and negative carbon, the sole condition being that the flame of the arc must touch or be projected by a magnet so as to touch this third carbon. We have, therefore, similar phenomena in the case of the arc and incandescence lamps.

(20.) When the electric arc is being projected against the third carbon, and has brought it down to the same potential, a galvanometer joined in between the two carbons shows no current; but this space between the negative carbon of the arc and the third carbon possesses a unilateral conductivity, and will pass the current from a small battery of secondary cells one way, but not the other. The secondary battery when joined in series with the galvanometer sends a current, if its negative pole is in connexion with the negative carbon of the arc, and its positive pole, through the

galvanometer, with the third carbon; but if the secondary battery is reversed in position it sends no current. Negative electricity can pass along the flame-like projection of the arc *from* the hot negative carbon *to* the cooler third carbon, but not in an opposite direction.

(21.) If the arc is projected by means of a magnet for a long time against the third insulated carbon, it *craters* it out in the same fashion as the crater of the positive carbon, and the tip of this third carbon, where it has received the flame-like blast of the arc, is converted into graphite.

The same effects are observed if an iron rod is used as a third pole, and in this case the end is converted into *steel*, and rendered so hard as to be scarcely touched by the file when it has been quenched in water.

In seeking for an hypothesis to connect together these observed facts, the one which suggests itself as most in accordance with the facts is as follows:—

In the case of a carbon incandescence lamp when at vivid incandescence, carbon particles are being projected from all parts of the filament, but chiefly from the negative half of [fol. 2722] the loop. These carbon molecules carry *negative* charges of electricity, and when they impinge upon a metal plate placed in the vacuum they can discharge themselves if this plate is positively electrified, either by being in metallic connexion with the positive electrode of the lamp or with a separate positively charged body. When the plate is simply insulated the stream of negatively charged carbon molecules brings down this insulated plate to the potential of the base of the negative leg, or to the potential of that part of the carbon conductor from which it is receiving projected molecules. These carbon molecules projected from an incandescent conductor can carry negative charges, but either cannot be positively charged, or else lose a positive charge almost instantly when projected off from the conductor.

In the case of the electric arc we must suppose that the negative carbon is projecting off a torrent of negatively electrified carbon molecules, and these, impinging against the positive carbon, wear out a crater in it by a sand-blast-like action.

The higher temperature of the positive carbon in a continuous current arc is thus explained as due to the impact of the carbon molecules projected from the negative carbon.

If the electric arc is diverted against a third insulated lateral carbon, the carbon blast from the negative carbon wears out a crater in it and brings it down to the same potential as itself. The actions going on in an electric arc may be considered to be somewhat as follows:—When the carbons are first put together, the resistance at the point of contact renders the extremities incandescent. When thus incandescent and separated, the electrification of each carbon is sufficient to begin the projection of molecules from both positive and negative carbons, probably most largely from the latter. The impact of the molecular stream from the negative pole raises the temperature of the positive carbon, and this again by radiation raises the temperature of the negative carbon end. The electromotive force is thus able to keep up a projection of negatively charged carbon molecules from the end of the negative carbon, which molecules are loosened from the mass by heat, and then move away by electric repulsion from the surface in virtue of the electric charge which they retain. It would seem as if a hot carbon molecule cannot retain a positive charge, and hence the potential difference between a third insulated carbon and the positive carbon of the arc is nearly the same as the potential difference of the positive and negative carbons of the arc. The rise of potential along the arc takes place very suddenly just in the neighbourhood of the crater of the positive carbon.

It has often been suggested that the electric arc contains a counter electromotive force. It is questionable whether such experiments as those of Edlund ('Phil. Mag.,' vol. 36, 1868, p. 352) are entirely conclusive on this point.

[fol. 2723] It has been shown by other experimenters * that for arcs of varying length, but the same current, beyond a certain small initial length, the potential difference necessary to maintain the arc is proportional to the length of the arc plus a constant. This might thus be interpreted to mean that a certain proportion of the work-electromotive force of the arc was employed in detaching the carbon molecules from the mass of the poles, and that the excess alone is represented by the current produced in an arc of definite length.

* See Professors Ayrton and Perry, "Proceedings of the Physical Society," vol. 5, p. 201.

In the case of the incandescence lamps the hypothesis of the projection of negatively charged carbon molecules from the incandescent conductor, to which the name of *molecular electrorection* may be given, will suffice to explain all the various different effects produced by varying the surface, position, and distance of the metal plate against which they impinge, and also the nullifying effect of shielding this plate from the negative leg of the carbon.

That this molecular discharge goes on chiefly from the negative leg is additionally proved by the greater erosion which takes place in the deposit of carbon on the negative leg when the carbon is uniform and traversed by a continuous current.

The hypothesis that a carbon molecule detached from an incandescent carbon surface in a high vacuum can only convey away a negative charge, reconciles also the above described observed effects in which a negative discharge can be made *out* of a hot surface of carbon more easily than a positive discharge. When an electromotive force is applied to two metallic terminal or electrodes sealed into a good vacuum, it is well known that a certain initial electromotive force has to be applied before any electric current begins to flow through the gas at all. It seems conclusively proved by Mr. Crookes's researches that the nature of an electric discharge through a high vacuum consists in a torrent of electrified particles proceeding from the negative electrode. If this is the case the initial electromotive force required to begin a discharge through such rarefied gas would naturally be reduced by heating the negative electrode, so as to favour and assist the detachment of the charged molecules of that electrode. The effect of heating the negative electrode in facilitating discharge through vacuous spaces has previously been described by W. Hittorf ('Annalen der Physik und Chemie,' vol. 21, 1884, p. 90-139), and it is abundantly confirmed by the above experiments. We may say that a vacuous space bounded by two electrodes —one incandescent, and the other cold—possesses a unilateral conductivity for electric discharge when these electrodes are within a distance of the mean free path of projection of the molecules which the impressed electromotive [fol. 2724] force can detach and send off from the hot negative electrode.

This unilateral conductivity of vacuous spaces having unequally heated electrodes has been examined by MM. Elster and Geitel (see 'Wiedemann's Annalen,' vol. 38, 1889, p. 40), and also by Goldstein ('Wied. Ann.,' vol. 24, 1885, p. 83), who in experiments of various kinds have demonstrated that when an electric discharge across a vacuous space takes place from a carbon conductor to another electrode, the discharge takes place at lower electromotive force when the carbon conductor is the negative electrode and is rendered incandescent.

"On the Conversion of Electric Oscillations into Continuous Currents by means of a Vacuum Valve." By J. A. Fleming, M.A., D.Sc., F.R.S., Professor of Electrical Engineering in University College, London. Received January 24.—Read February 9, 1905.

An electric oscillation being an alternating current of very high frequency, cannot directly affect an ordinary movable coil or movable needle galvanometer.

Appliances generally used for detecting electric waves or electric oscillations are, therefore, in fact alternating current instruments, and must depend for their action upon some property which is independent of the direction of the current, such as the heating effect or magnetizing force. The coherer used in Hertzian wave research is not metrical, since the action is merely catastrophic or accidental, and bears no very definite relation to the energy of the oscillation which starts it. Even the demagnetising action of electric oscillations, though more definite in operation than the contact action at loose joints, is far from being all that is required for quantitative research. It is obvious it would be an advantage if we could utilize the direct current mirror galvanometer for the detection and measurement of feeble electric oscillations. This can be done if we can discover a medium with perfect unilateral conductivity.

Some time ago, I considered the use of the aluminium-carbon electrolytic cell with this object. It is well known that a cell containing a plate of aluminium and carbon, immersed in some electrolyte which yields oxygen, such as

dilute sulphuric acid or an aqueous solution of any caustic alkali, or salt yielding oxygen, has a unilateral conductivity within limits. An electric current under a certain electromotive force can pass through the cell from the carbon to the aluminium, but not in the reverse direction.

This action has been much studied and is the basis of many technical devices, such as the Nodon electric valve.

The electrochemical action by which this unilateral conductivity is produced involves, however, a time element, and after much experimenting I found that it did not operate with high frequency currents. My thoughts then turned to an old observation made by me in 1889, communicated to the Royal Society, amongst other facts, in a Paper in 1889, and also exhibited experimentally at the Royal Institution in 1890.* This was the discovery: that if a [fol. 2726] carbon filament electric glow lamp contains a pair of carbon filaments or a single filament and a metallic plate sealed into the bulb, the vacuous space between possesses a unilateral conductivity of a particular kind when the carbon filament, or one of the two filaments, is made incandescent. I have quite lately returned to this matter, and have found that this unilateral conductivity exists even with alternating currents of high frequency and is independent of the frequency. Hence, in a suitable form, it seemed possible that such a device would provide us with a means of rectifying electric oscillations and making them measurable on an ordinary galvanometer. The following experiments were, therefore, tried:—

Into a glass bulb, made like an incandescent lamp, are sealed in the ordinary way two carbon filaments, or there may be many filaments. On the other hand, one carbon filament may be used and a platinum wire may be sealed into the bulb terminating in a plate or cylinder of platinum, aluminium or other metal surrounding the filament. It is

* See 'Roy. Soc. Proc.,' vol. 47, p. 122, 1890, "On Electric Discharge between Electrodes at different Temperatures in Air and High Vacua," by J. A. Fleming, communicated December 16, 1889; see also 'Proceedings of the Royal Institution,' vol. 13, Part LXXXIV, p. 45, Friday evening discourse on February 14, 1890, "Problems on the Physics of an Electric Lamp," when this unilateral conductivity was experimentally shown.

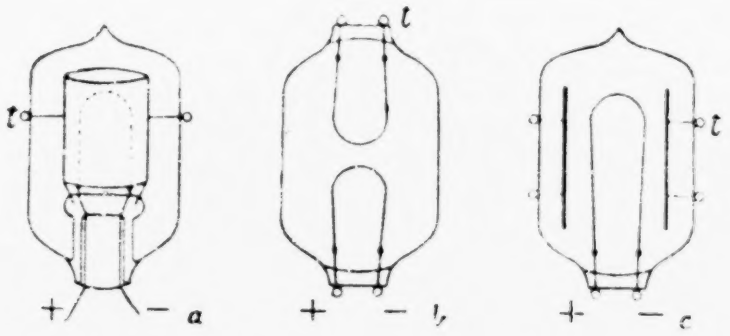
preferable to use a metal plate carried on a platinum wire sealed into the glass bulb, the plate being bent into a cylinder which surrounds both the legs of the carbon loop. The diagrams in fig. 1 show various forms of the arrangement. Diagram *a* shows a bulb with a single carbon filament surrounded by a metal cylinder, *b* shows one with two carbon filaments, and *c* a carbon filament and two insulated metal plates. The ends of the carbon filament which is rendered incandescent are marked + and − and the terminal of the other electrode of the valve is marked *t*. The bulb must be highly exhausted to about the pressure usual in the case of carbon filament incandescent lamps, and the metal cylinder or plate must be freed from occluded air.

Suppose that we employ such a bulb containing one carbon filament surrounded by a metal cylinder (see *a*, fig. 1). The filament may be of any voltage, but I find it most convenient to employ filaments of such a length and section that they are brought to bright incandescence by an E.M.F. of 12 volts. The voltage and section of the filament should be so arranged that the temperature of the filament corresponds with an "efficiency," as a lamp-maker would say, of 2·5 or 3 watts per candle. The filament is conveniently brought to incandescence by a small insulated battery of secondary cells. A circuit is then completed through the vacuous space in the bulb between the cylinder and the filament by another wire which joins the external terminal of the metal cylinder and that terminal of the carbon filament which is in connection with the negative pole of the heating battery. In this last circuit is placed a sensitive mirror galvanometer of the movable needle or movable coil [Sol. 2727] type, and also a coil which may be the secondary circuit of an air core transformer in which electric oscillations are set up. As is now well known, the vacuous space in the bulb permits negative electricity to move in it from the hot filament or cathode through the vacuous space to the cylinder or anode and back through the galvanometer or coil, but not in the reverse direction, as long as the cylinder is cool and the carbon filament not at a temperature much above the melting point of platinum. To illustrate the action of the bulb as an electrical valve, the following experiments can be shown:

Electric oscillations are set up in a metal wire circuit by the discharge of a Leyden jar, as usual. This circuit

takes the form of a thick wire of one or more turns, bent into the form of a circle or square. Some distance from this, we place another wire, of several, say eight or ten

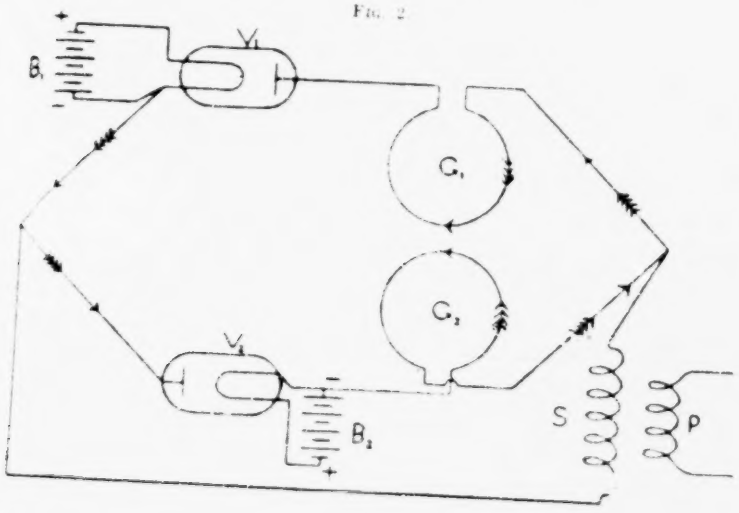
Fig. 1.



turns, also bent into the form of a circle, and connect this last wire into the circuit of a galvanometer and vacuum bulb made as described, so that it is a circuit having unilateral conductivity. On exciting the oscillations in the primary circuit by an induction coil we have an alternating high frequency magnetic field produced, which affects the secondary circuit at a distance. The oscillations in this last are, however, able to flow only in one direction. Hence, the galvanometer is acted upon by a series of intermittent but unidirectional electromotive forces, and its needle or coil deflects. Since the field is a high frequency field, we can show the screening effect of a sheet of tin foil or silver paper in a very simple and effective manner by the effect it produces in cutting down the galvanometer deflection when the metal sheet is interposed between the primary secondary circuits. Also, if we move the secondary coil away from the primary coil or turn the two coils with their planes at right angles to one another, then the galvanometer deflection diminishes or falls to zero because the induction is decreased. Accordingly, we have in this vacuum valve and associated [fol. 2728] mirror galvanometer a means of detecting feeble alternating electric currents or oscillations. Another method is to employ a differential galvanometer and two vacuum valves. These must then be arranged, as shown in fig. 2, one circuit G_1 of the differential galvanometer is in series with one valve V_1, and the other circuit G_2, with the other valve V_2, but so joined up that currents flowing through the valves in opposite directions pass round the two galvanom-

eter wires in the same direction as regards the needle and, therefore, their effects are added together on the galvanometer needle. Each valve must then have its own separate insulated battery to ignite the filament. Also, it is necessary that the connection with the oscillatory circuit must be made in both cases to the hot filament by that terminal which is in connection with the negative pole of the local battery used to ignite the filament (see fig. 2).

FIG. 2.



This arrangement of a differential galvanometer and two valves transforms, of course, more of the alternating oscillation into direct current than when one valve alone is used. It provides us with a means of detecting electrical oscillations not merely in closed circuits but in open electrical circuits.

When so using it, it is necessary to associate with the oscillation valve and galvanometer an oscillation transformer for raising the voltage. The resistance of these valves, when in operation, may be anything from a few hundred ohms up to some megohms, depending on the state of incandescence of the filament and upon the electromotive force employed to drive the current through the vacuous space, as well as upon the size of the filament and [fol. 2729] the plate. This resistance does not obey Ohm's law, but the current increases to a maximum and then slightly decreases as the voltage progressively increases. The form of oscillation transformer employed with the device is as follows: A small air-core induction coil has

a primary circuit, which consists of 52 turns of gutta-percha covered wire, wound in a helical groove cut on an ebonite rod 0·5 inch in diameter and 6 inches in length. The primary circuit is made of a No. 20 or No. 22 S.W.G. copper wire. The secondary circuit consists of 36,000 turns of fine silk-covered wire, No. 36, wound in six coils, each having about 6000 turns, and all joined in series. This secondary circuit has one terminal connected to one common terminal of the galvanometer and the other to the common terminal of the two oscillation valves (see fig. 4). The primary coil of this oscillation transformer has one terminal connected to earth and the other to a long insulated rod which acts as an aerial or electric wave collector. To prevent the direct action of the transmitter upon the secondary coil by simple electromagnetic induction, it is best to wind the secondary coil in two equal parts in opposite directions and to wind the primary in a corresponding manner.

If an electric wave sent out from a similarly earthed transmitter falls upon the rod, then an electrical oscillation is set up in the receiving circuit and therefore in the primary coil of the oscillation transformer inserted in series with it. This oscillation is raised in voltage by the secondary coil of the transformer, and by reason of the unilateral conductivity of a vacuum valve, placed in series with the coil, one part of the oscillation, viz., the positive or the negative current, passes round the galvanometer coils and affects it.

If we employ a sensitive dead beat galvanometer of the type called by cable engineers a "Speaking Galvanometer," then intelligible signals can be sent by making small and larger deflections of the galvanometer corresponding to the dot and dash of the Morse alphabet; anyone who can "read mirror" can read off the signals as quickly as they can be sent on an ordinary short submarine cable with this arrangement.

The arrangement, although not as senitive as a coherer or magnetic detector, is much more simple to use. Also it has one great advantage, viz., that it enables us to examine the behaviour of any particular form of oscillation producer. By means of it we can detect changes in the wave making power or uniformity of operation of the transmitting arrangement, by the variation of the deflection of the galvanometer. Thus, for instance, if a spark-ball transmitter is being employed and the deflection of the galvanometer in association with the receiving aerial is steady, if we put the

slightest touch of oil upon the spark-balls of the transmitter, their wave-making power is increased and the deflection of the galvanometer at once increases. Since the current through the galvanometer is the result of the groups [fol. 2730] of oscillations which are created in the receiving circuit, and since in the ordinary transmitter these oscillation groups are separated by wide intervals of silence, it is obvious that we can increase the sensitiveness of the above described arrangement by employing a very rapid break or interruptor with the induction coil. If, for instance, we employ a Wehnelt break with the induction coil or a high speed mercury break or alternating current transformer, we get a far better result as indicated by the deflection of the galvanometer than when employing the ordinary low frequency spring or hammer break.

The point of scientific interest in connection with the device, however, is the question how far such unilateral conductivity as is possessed by the vacuous space is complete. The electrical properties of these vacuum valves have accordingly been studied.

A bulb containing a 12 volt carbon filament rendered brightly incandescent by a current of about 2.7 to 3.7 amperes was employed. The filament was surrounded by an aluminium cylinder. The length of the carbon filament was 4.5 cm., its diameter 0.5 mm., and surface 70 square mm.

The aluminium cylinder had a diameter of 2 cms., a height of 2 cms., and a surface of 12.5 square cms. The filament was shaped like a horse shoe, the distance between the legs being 5 mm. This filament was rendered incandescent to various degrees by applying to its terminals 8, 9, 10, and 11 volts respectively. Another insulated battery of secondary cells was employed to send a current through the vacuous space from the cylinder to the filament, connection being made with the negative terminal of the latter. The current through the vacuous space and the potential difference of the cylinder and negative end of the hot carbon filament were measured by a potentiometer. The effective resistance of the vacuous space is then taken to be the ratio of the so observed potential difference (valve P.D.) to the current (valve current) through the vacuum.

The following table records the observations. The column headed P.D. gives the potential difference between the hot filament and the cylinder, that headed A gives the

current through the vacuous space in milliamperes, that headed R the resistance of the space in ohms, and that headed $K10^6$ is 1000,000 times the conductivity.

The result is to show that the vacuous space does not possess a constant resistance, but its conductivity increases rapidly up to a maximum and then decreases as the valve potential difference progressively increases. If we plot the current-values as ordinates and potential difference of the valve electrodes as abscissæ, we find that the current curve quickly rises to a maximum value and then falls again slightly as the potential difference increases steadily. The conductivity curve also rises to a maximum and then decreases (see fig. 3).

The facts so exhibited are well-known characteristics of [fol. 2731] gaseous conduction in rarefied gases.* It may be noted that there is in these current-voltage and voltage

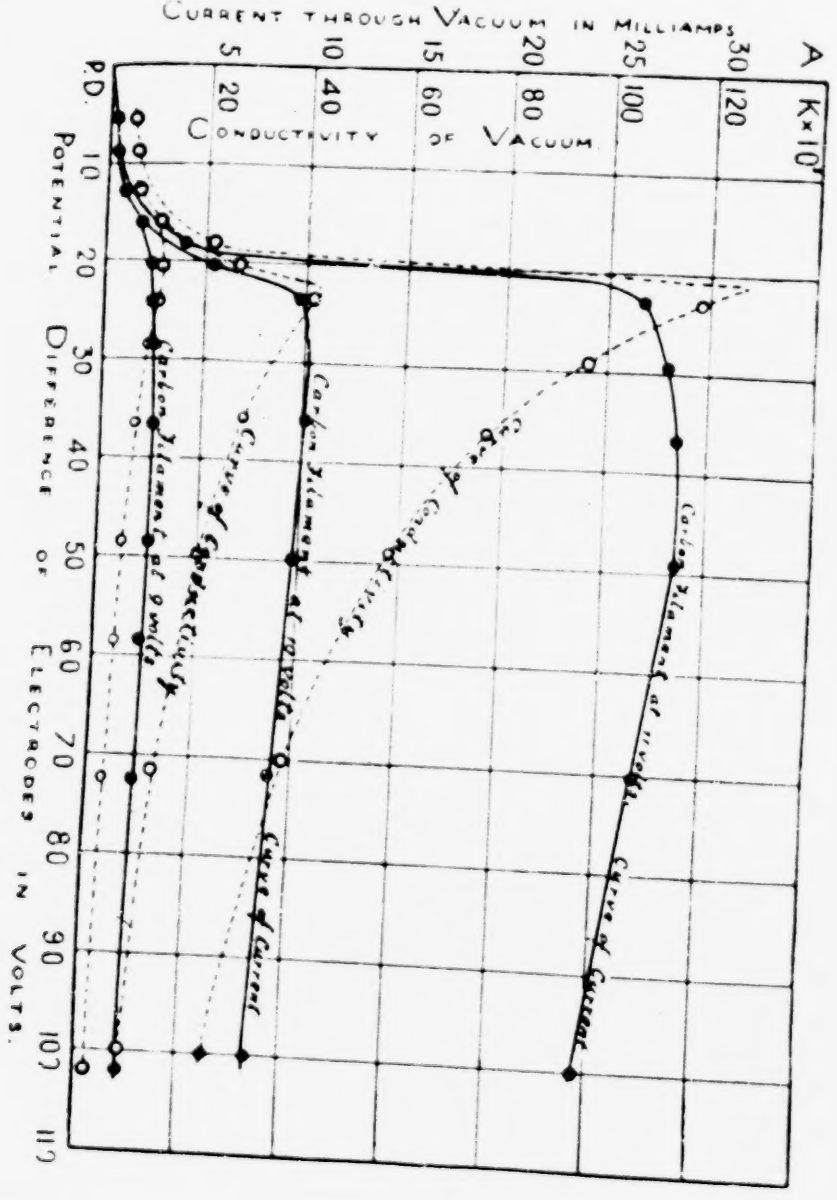
* See J. J. Thomson, 'Conduction of Electricity through Gases,' Chap. VIII.

conduction curves a general resemblance to the magnetisation and permeability curves of iron.

To examine further the nature of this conduction, the following experiments were made. If a vacuum bulb, as described, is joined up in series with a galvanometer and an electrodynamometer and an alternating electromotive force applied to the circuit, the two instruments will be both affected. The galvanometer is, however, affected only by

FIG. 3



[fol. 2732] the resultant flux of electricity in one direction. It measures the unidirectional current. The dynamometer is affected by the bilateral flux of electricity and it measures the total or alternating current. If, therefore, the vacuous space is totally non-conducting in one direction, one half [fol. 2733] of the alternating current will be cut out. The galvanometer will read the true mean (T.M.) value of the remanent unidirectional current, and the dynamometer will read the root-mean-square (R.M.S.) value. If the conductivity in one direction is not zero, then the galvanometer will read the T.M. value of the difference of the positive and negative currents, but the dynamometer will read the R.M.S. value of their sum.*

In the last case, the current through the valve may be considered to be a continuous current superimposed upon an alternating current.

If we call I the maximum value of the nearly sinoidal current in one direction, and I′ the maximum in the opposite direction, then we may say that the dynamometer reading (D) expressed in true current value is equal to $g\,(\mathrm{I}+\mathrm{I}')$ where g is the *amplitude factor*, and also that the galvanometer reading (G) in true current value is equal to $g\,f\,(\mathrm{I}-\mathrm{I}')$, where f is the *form factor* of the current.† Hence—

$$\frac{\mathrm{D}}{\mathrm{G}} = f\frac{\mathrm{I}+\mathrm{I}'}{\mathrm{I}-\mathrm{I}'}, \text{ or } \frac{\mathrm{D}}{\mathrm{G}}\frac{2f}{+f} = \frac{\mathrm{I}}{\mathrm{I}-\mathrm{I}'}.$$

The fraction $\frac{2f}{\mathrm{D}\,\mathrm{G}+f}$, say B_1 expressed as a percentage may be called the *rectifying* power of the valve, for it expresses the percentage which the actual unilateral electric flow or continuous current through the valve is of that con-

---

* If i is the instantaneous value of a periodically varying current with maximum value I and periodic time T, then the root-mean-square value (R.M.S. value) of i is defined to be $\left(\frac{1}{\mathrm{T}}\int_0^{\mathrm{T}} i^2 dt\right)^{\frac{1}{2}}$ and the true mean value (T.M. value) of i is defined to be $\frac{2}{\mathrm{T}}\int_0^{\frac{1}{2}\mathrm{T}} i\,dt$.

† The *form factor* f and *amplitude factor* g are the names given by the author (see 'Alternating Current Transformer,' J. A. Fleming, vol. I. p. 585, 3rd edit.) to the ratio of the R.M.S. to the T.M. value of the ordinates of a single valued periodic curve, and to the ratio of the R.M.S. value of the ordinates to the maximum avlue during the period.

tinuous current which would flow if the unilateral conductivity were perfect.

Perfect rectifying power, however, does not exist. There is not an infinite resistance to movement of negative electricity from the metal cylinder to the hot filament through the vacuum, although this resistance is immensely greater than that which opposes the movement of negative electricity in the opposite direction. This point was examined, as follows: A very sensitive electrodynamometer was skilfully constructed by my assistant, Mr. G. B. Dyke, the fixed coil having 2000 turns of No. 47 silk-covered copper wire and the movable coil 1000 turns. The suspension of the movable coil was by a fine flat phosphor-bronze wire at top and bottom. The deflection was observed by a mirror and scale.

[fol. 2734] This dynamometer was placed in series with a shunted movable coil galvanometer of Holden-Pitkin pattern, and the two together placed in series with a variable section of an inductionless coil through which an alternating current was passing. A vacuum valve as above described was in series also with the galvanometer and dynamometer. The alternating current was derived from an alternator giving a nearly true sinoidal electromotive force. The form factor of the electromotive force curve of this alternator was determined and found to be 1.115, that for a true sine curve being 1.111.

The vacuum valve sifted out the alternating current flow and allowed the currents in one direction to pass, but nearly stopped those in the opposite direction. The indications of the electrodynamometer were proportional to the root-mean-square (R. M. S.) value of the sum of the two opposite currents, and that of the galvanometer to the true mean value (T. M.) of their difference. The galvanometer and dynamometer were both calibrated by a potentiometer by means of continous current, and curves constructed to convert their scale readings to milliampères. Then with various alternating current electromotive forces, their readings were taken when in series with a vacuum valve and recorded in the following tables. The letter D denotes current in milliampères as read by the so calibrated dynamometer and G that read by the galvanometer. The ratio D/G is denated by s, and the rectifying power, viz., $2f \cdot s - f$ by p.

The table shows that the value of α is not constant, but for each state of incandescence of the filament reaches a maximum which, however, does not greatly differ from the mean value for the range of currents used. If we set out the mean values of β in a curve (see fig. 4), in terms of the power expended in heating the carbon filament, we see that the rectification is less complete in proportion as the temperature of the carbon filament increases. This is probably due to the fact that as the filament gets hotter, it heats the enclosing cylinder to a higher temperature and enables negative electricity to escape from the latter.

Hence, I feel convinced that if the metal cylinder could be kept quite cool by water circulation the rectification would reach 100 per cent. or be complete.

An ideal and perfect rectifier for electric oscillations may, therefore, be found by enclosing a hot carbon filament and a perfectly cold metal anode in a very perfect vacuum. With a bulb such as that used for the above experiments all we can say is that the current passed through the vacuum is from 80 to 90 per cent. continuous, 100 per cent. implying that the vacuum is perfectly non-conducting in one direction and permits the flow of negative electricity only from the hot to the cold electrode. The necessity for keeping the cathode cold is shown by the following experiment:—An alternating-current arc was formed between

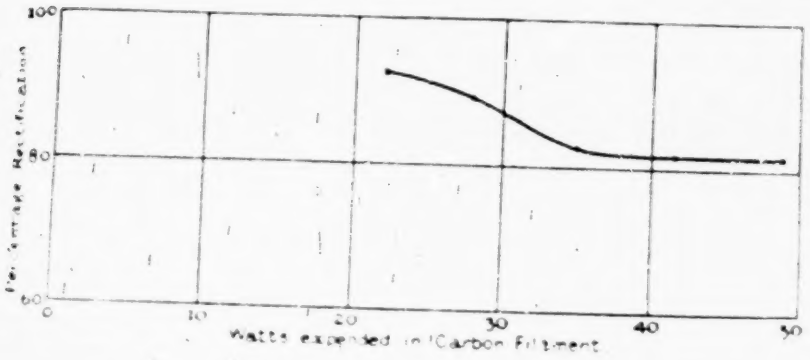
carbon rods, and an iron rod was placed so that its end dipped into the arc. An ammeter was connected in between either carbon and the iron rod, and indicated a continuous current of negative electricity flowing through the ammeter from the iron rod to the carbon pole. This current was, however, greatly increased by making the iron rod of a piece of iron pipe closed at the end and kept [fol. 2736] cool by a jet of water playing in the interior. In this manner I have been able to draw off a continuous current of 3 or 4 ampères from an alternating-current arc using 15 alternating-current ampères.

Returning, then, to the vacuum valve, we may note that the curves in fig. 3 show that the vacuous space possesses a maximum conductivity corresponding to a potential difference of about 20 volts between the electrodes, for the particular valve used. The interpretation of this fact may, perhaps, be as follows:—In the incandescent carbon there is a continual production of electrons or negative ions by atomic dissociation. Corresponding to every temperature there is a certain electronic tension or percentage of free electrons. If the carbon is made the negative electrode in

FIG. 4



a high vacuum these negative ions are expelled from it, but they cannot be expelled at a greater rate than they are produced. Therefore, there is a maximum value for the outgoing current and a maximum value for the ratio of current to electromotive force, that is for the conductivity.

This fact, therefore, fixes a limit to the utility of the device. The current through the vacuous space is, to a very large extent, independent of the electromotive force creating it, and is at no stage proportional to it, or at least only within a narrow range of electromotive force near to the maximum conductivity.

Whilst, therefore, the device is useful as a simple means of detecting electric oscillations, it has not that uniformity of conductivity which would make it useful as a strictly metrical device for measuring them. It can, however, perform the useful service of showing us how far any device for producing electric oscillations or electric waves produces a uniform or very irregular train of electric oscillations, and what changes conduce to an improvement or reduction in the efficiency of the transmitting device.

UNITED STATES PATENT OFFICE.

LEE DE FOREST, OF NEW YORK, N. Y.

DEVICE FOR AMPLIFYING FEEBLE ELECTRICAL CURRENTS.

No. 841,387. Specification of Letters Patent. Patented Jan. 15, 1907.

Application filed October 25, 1906. Serial No. 340,487.

To all whom it may concern:

Be it known that I, LEE DE FOREST, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented a new and useful Improvement in Devices for Amplifying Feeble Electrical Currents, of which the following is a specification.

My invention relates to devices for amplifying feeble electrical currents—such, for example, as telephone-currents; and its object is to produce an amplifying device of greater efficiency and simplicity than those heretofore employed.

My invention will be described with reference to the drawings accompanying and forming a part of this specification, and in which—

Figures 1, 2, 3, 4, 5, 6, and 7 represent conventionally or diagrammatically various arrangements of apparatus and circuits whereby my invention may be carried into effect.

In the figures, A represents an evacuated vessel inclosing a sensitive conducting gaseous medium maintained in a condition of molecular activity.

R is a signal-indicating device.

B B are batteries or other sources of electrical energy.

D E D′ are electrodes sealed within the receptacle A.

The circuit B R D E is a local receiving-circuit. The circuit F is a line-circuit conveying the currents to be amplified to the amplifying device. The electrode E, which may be of platinum, tantalum, carbon, or other suitable material, is heated and preferably maintained incandescent by the battery B′. The electrodes D and D′, which may be plates of platinum or other suitable material, are placed in close proximity to the electrode E, and when the electrode D′ is employed its separation from the electrode E preferably is less than that of the electrode D therefrom.

In Fig. 1, N S represent a magnet placed adjacent to the vessel A. The currents to be amplified may be impressed upon the circuit which includes the heated electrode or filament E—as, for example, by means of the transformer M—and the magnetic field set up by these currents reacts upon the field set up by the magnet N S, thereby causing a slight variation in the separation between the electrodes D E. I have found that the slightest variation in the separation of the hot and cold electrodes produces a large and disproportionately greater variation in the flux between said electrodes, especially if the latter are close together, and such variation in flux may be made manifest by the signal-indicating device R.

In Fig. 2 the current to be amplified may be impressed upon the medium intervening between the electrodes D and E, and thereby alter, by electrostatic attraction, the separation between the electrodes. In this case D′ may be a strip of platinum-foil, and the slightest approach thereof toward the filament will act to slightly cool the gaseous medium, and thereby alter the current in the local circuit, or, if D′ is rigid, the increase in electrostatic attraction between D′ and E will cause E to recede from D, and thereby alter the current in the local circuit.

In Fig. 3 the filament E is connected, by means of a minute platinum wire I, to the arm J which is secured to the coil *a*, placed between the poles of the magnet H and secured to the walls of the vessel A through the spiral springs *b b*. The line-current to be amplified in this case is passed through the coil *a* through the springs *b b*, and the resulting rotation of the coil varies the separation between the electrodes D E, thereby altering the current in the local circuit.

In Fig. 4 the currents to be amplified may be impressed upon the gaseous medium intervening between D′ and E by means of the transformer M′. A condenser C may be included in series with the secondary of said transformer and the electrodes D′ E. In this case there may or may not be a variation between the separation of the electrodes, and the currents to be amplified may vary the motions of the ions around the filament, thereby controlling to a greater degree the flux between said filament and the electrode D.

In Fig. 5 the currents to be amplified may be passed through the solenoid surrounding the magnet N S, and thereby vary the field, which by coacting with the magnetic field surrounding the electrode E determines the normal separation of the electrodes D and E. Even without creating actual movements between the electrodes D and E the varying magnetic flux produced by the line-current passing through the solenoid L will affect the motion of the ions in the gaseous medium, and thereby alter the current in the local circuit.

In Fig. 6 the electrode D may be consti-

2739

tuted of iron or may consist of platinum plates provided with small iron armatures G G. In either case the currents to be amplified by passing through the solenoids P P, which surround the poles of the magnet N, effect the desired variation in the separation of the electrodes D and E.

In Fig. 7 the electrode D and diaphragm S may both be rigidly secured to the inside and outside, respectively, of the glass wall of the vessel A at a point where said wall has been flattened and made very thin, like the crystal of a watch. The currents to be amplified in this case by operating upon the coils P' P', surrounding the magnet Q, effect slight movements of the diaphragm S, and these movements are mechanically transmitted through the glass wall of the vessel A to the electrode D, thereby varying the current in the local receiving-circuit.

It will be obvious that the amplifying device which constitutes the subject-matter of the present invention is not limited in its use to any particular kind of electrical circuit or apparatus, but that it is capable of general application wherever an amplifying device is required. By way of example of its application to a wire telegraph or cable system I have shown the line F in Fig. 1 as including a telegraph transmitting-key T and source of vibratory current G. In Fig. 2 I have shown the line F as constituting the local circuit of a wireless telegraph receiving system including the battery B and oscillation detector D, the latter being connected in series with an antenna V and the earth E. In Fig. 4 I have shown the line F as constituting a telephone circuit including the microphone-transmitter T and battery B. In all instances it will be understood by those skilled in the art and without going into further detail that the signal-indicating device R, which is included in the local receiving-circuit, may be any device suitable for the purpose of reproducing the signal initiated in the line F.

I do not limit myself to any of the specific embodiments of my invention herein described, inasmuch as many modifications may readily occur to those skilled in the art without departing from the principle of my invention.

I claim—

1. In a device for amplifying electrical currents, an evacuated vessel, two electrodes sealed within said vessel, means for heating one of said electrodes, a local receiving-circuit associated with said electrodes, and means whereby the separation of said electrodes may be varied by the currents to be amplified.

2. In a device for amplifying electrical currents, an evacuated vessel, two electrodes sealed within said vessel, means for heating one of said electrodes, a local receiving-circuit associated with said electrodes, and means whereby the separation of said electrodes may be varied by the currents to be amplified.

3. In a device for amplifying electrical currents, an evacuated vessel, two electrodes sealed within said vessel, a circuit including a source of electric energy connected in series with one of said electrodes, a local receiving-circuit associated with said electrodes, and means whereby the separation of said electrodes may be varied by the currents to be amplified.

4. In a device for amplifying electrical currents, an evacuated vessel, three electrodes sealed within said vessel, means for heating one of said electrodes, a local receiving-circuit including two of said electrodes, and means for passing the current to be amplified between one of the electrodes which is included in the receiving-circuit and [illegible] electrode.

5. In a device for amplifying electrical currents, an evacuated vessel inclosing a gaseous medium, means other than the received energy for maintaining said gaseous medium in a condition of molecular activity, means for impressing the currents to be amplified upon said gaseous medium, and a local receiving-circuit having its electrodes sealed within said vessel.

6. In a device for amplifying electrical currents, an evacuated vessel, a heated electrode and two non-heated electrodes sealed within said vessel, the non-heated electrodes being unequally spaced with respect to said heated electrode, a local receiving-circuit including said heated electrode and that one of the non-heated electrodes which has the greater separation from the heated electrode, and means for varying the current to be amplified between the heated electrode and the other non-heated electrode.

In testimony whereof I have hereunto subscribed my name this [illegible] day of [illegible], 1906.

metal-copper pyrites, metal-chalcocite, metal-manganese dioxide, metal-tellurium. He proved that:

1. These detectors are sensitive only if the contact is limited to a point.

2. They operate without a battery in series, and when a battery is used the sensitiveness does not depend upon the value or direction of its e.m.f.

3. The direction of the current (direct) obtained under the influence of the received oscillations is always the same as the direction of the thermo-e.m.f.

With another group, however—carborundum, anatase (titanium dioxide), molybdenite and the perikon detector—TISSOT's tests established that:

1. The form of the contact is of little or no importance, even relatively large polished plates placed between two metallic electrodes make sensitive detectors.

2. The use of a battery in series with the detector, with proper value and direction of the battery e.m.f., increases the sensitiveness.

3. The sensitiveness of these detectors bears no relation whatever to the value of their thermo-e.m.f.

He, therefore, concludes that in this last mentioned group thermo-electric forces play no important part in their action as detectors.

G. W. PIERCE,[1] as the result of extensive investigations, including oscillograph records made with the BRAUN tube, concluded that with carborundum, anatase, brookite (another form of TiO_2) and silicon, thermoelectric forces were not involved, but that these detectors were better conductors in one direction than in the other, in short, act as *rectifiers* [Art. 162].

161. Incandescent Lamp Detectors, Gas Detectors.—*a.* J. A. FLEMING[264] observed the following phenomenon: An electrode (A, Fig. 340), say of cylindrical form, is fused into an incandescent lamp bulb, whose filament is made incandescent by means of a battery, B.* A circuit containing a galvanometer, G, (or telephone) and a coil, S_2, is joined to the electrode, A, at one end and to the lamp filament, at the other, K. The aerial coil S_1 is coupled with S_2; hence if oscillations pass through S_1, the oscillations induced in the circuit AGS_2K will cause the galvanometer to deflect (or produce a sound in the telephone). The galvanometer needle will return to its zero position as soon as the oscillations cease, *i.e.*, the arrangement is a self-restoring wave indicator.

Several years ago C. TISSOT[265] used this wave indicator for measurements over considerably long ranges but he complains of the irregularity

* A choke coil [Art. 163] should be inserted in the leads from the battery to the lamp.

Claimant's Exhibit No. 275 3161

of the deflections.* But in the more recent form of FLEMING's "oscillation-valve," the anode being a cylinder of carbon and the cathode a tungsten wire, this detector seems to have met all reasonable requirements as to sensitiveness and reliability. This is borne out by the fact that MARCONI has been using it, in conjunction with an EINTHOVEN string galvanometer, in his transatlantic stations.

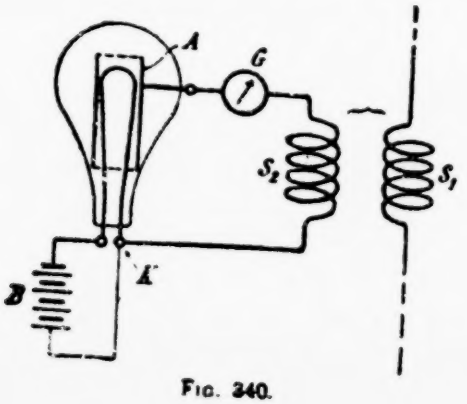

FIG. 340.

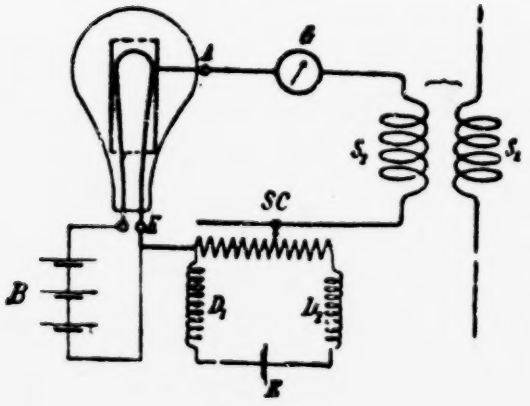

FIG. 341.

The incandescent lamp may be replaced by the tube devised by A. WEHNELT[266] which operates in the same manner. The incandescent cathode of this tube is a wire coated with a metallic oxide, and the anode is a hollow aluminium cylinder, concentric with the cathode.

b. H. BRANDES[267] has found that it is very advantageous to insert an auxiliary battery or cell, *E*, about as shown in Fig. 341,† when using

* TISSOT[265] describes a wave indicator using rarified air (as in the ZEHNDER tube), which he found to be less sensitive but better adapted for measuring purposes.

† D_1 and D_2 are inductive coils.

[fol. 2745] PLAINTIFF'S EXHIBIT 276

Chapter III

Valve Detectors and Detector Relays

In the previous Chapter it has been pointed out that the plate current curve of a hard valve is of such a shape that the valve has got rectifying properties. When functioning as a detector at the lower bend of the curve the grid potential in the general case is negative compared with the filament and the grid current is zero; the grid circuit has infinite resistance and hence the valve abstracts no energy from the oscillating circuit to which it is connected, the necessary pulses of telephone current coming from the plate circuit battery. *Thus a valve employed in this way as a detector has very little damping effect on the oscillating circuit*, therefore tuning will be sharp, and loose coupling to the aerial circuit can be employed so that jamming by interference is reduced.

The damping effects of the valve are not entirely zero, for there is a small capacity effect between the grid and the other electrodes which allows some oscillating energy to pass; on account of this the valve may not be as good a detector as a good crystal on short waves at high frequencies.

Before discussing further the methods of using a hard valve for rectification it may be interesting to briefly consider some of the earlier types of valves which were used on wireless receiver circuits.

Fleming Valve.—The first valve detector was patented by Dr. J. A. Fleming in 1904; it had no grid, and simply made use of the unilateral conductivity effect between a heated filament and a plate enclosed together in a vacuum. At that time it was considered so reliable and robust compared to crystal detectors that it was largely adopted on wireless installations by the Marconi Company.

The detector consisted of a small electric lamp with a single hairpin filament of tungsten or carbon, surrounded by a cylinder of sheet or gauze copper, or nickel, which was attached to a third terminal on the lamp.

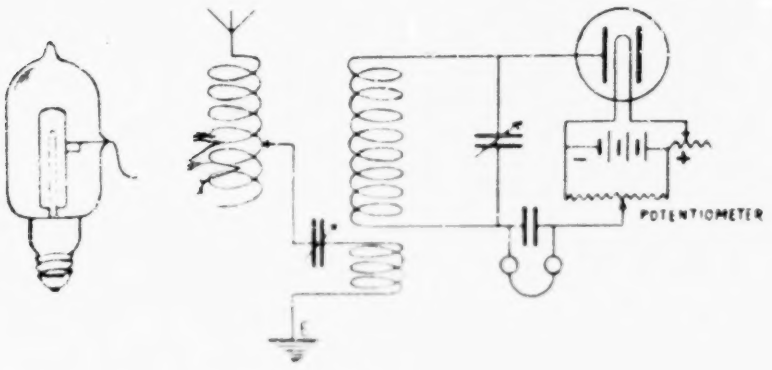
[fol. 2746] The filament was heated to incandescence by means of a battery, of from 4 to 12 volts depending on the size of the valve, in series with a regulating resistance. The

negative side of the filament was connected in series with a potentiometer voltage and telephone receivers to one side of the wireless receiver circuit, the copper plate or anode to the other side of the circuit.

The valve had a soft vacuum and was what we would now call a "gas valve"; its sensitiveness to signals was not so good as that of a good crystal combination, but the sensitiveness was not impaired by strong signals and atmospherics.

Fig. 12 shows a Fleming Valve as supplied by the Marconi Company: also its connections to a receiving circuit.

Fleming was the first to use the unilteral conductivity



effects of an electron discharge, from a heated filament to a plate at a higher potential than the filament, so that his patent may be considered as the parent one of all valves used in wireless receiver circuits.

Lieben Reisz Valve. The use of a grid between the plate and filament seems to have been first applied commercially by Lieben and Reisz in their valve relay, which was used by them for relaying low frequency, or telephonic, current pulses. It is described in Chapter VI, dealing with Low Frequency Amplification.

"Audion" Valve.—Dr. De Forest introduced a grid consisting of a perforated cylinder, or plate, between the filament and anode of what was virtually a Fleming valve, thus producing a relaying valve which he called an {fol. 2747} "Audion." In De Forest's circuit, which is shown in Fig. 13, the valve is used as a detector relay; the small pulses of potential set up in the receiver circuit act on the grid and cause corresponding pulses of plate circuit

current; these are also rectified by employing the valve at the proper point on its characteristic curve.

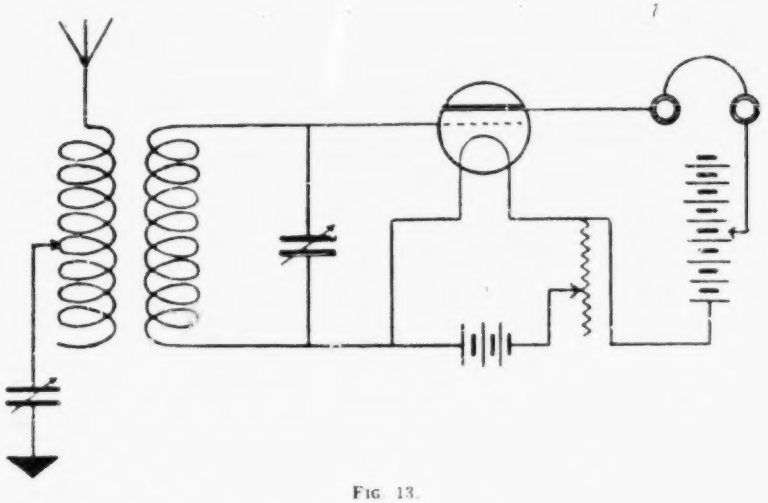


FIG. 13.

Round's Valve.—The soft vacuum Round valve was much superior to any which had preceded it, and was of such a size that comparatively large current pulses were dealt with in the plate filament circuit. It had a hairpin platinum filament coated with a mixture of barium and calcium oxides; completely surrounding the filament was a thimble of fine mesh nickel wire which formed the grid, while a nickel cylinder surrounded this again to form the plate. Like all soft valves it was very sensitive to grid potential, which was regulated by a potentiometer in series with the grid; it was also very sensitive to the degree of vacuum, in other words its sensitiveness depended greatly on the ionisation effects, as has been described in the previous Chapter.

In order to counteract the tendency of the valve to harden with continued use a pellet of asbestos was enclosed in a small neck at the top of the valve; heating this by a match would drive from it gas molecules into the body of the valve, and thus the vacuum could be brought to the proper degree of softness. The necessity of thus regulating the vacuum was a disadvantage, also the facts that when started up the valve did not come into proper

COMPLETE SPECIFICATION.

Improvements in Means of Telegraphing or Telephoning without Wires.

ALFRED CHARLES BROWN, Electrician, and GEORGE RICHARD NEILSON, Secretary to Public Company, both of 50 Old Broad Street in the County of London do hereby declare the nature of this invention and in what manner the same is to be performed, to be particularly described and ascertained in and by the following statement:—

It has been known for some time past that waves of Electric energy of certain periodicities or numbers of vibrations per second, known usually as Hertzian waves, are capable of being radiated or projected so as to act on other Electric circuits placed at a distance, and produce certain effects therein, such as sparking between disconnected conductors, and the alteration in resistance of loose contacts or "Coherers" *etc.* It has been known too that these effects are manifested through considerable distances in space and through various media which are in some cases opaque to ordinary light.

The purpose of the present invention is to render the above-mentioned phenomena more practicably applicable to certain purposes of signalling, and for Telephoning without wires.

For this purpose when a signalling Telegraph only is required we provide at, or in connection with, the Transmitting Station a set of Apparatus for producing the rays, such as a current generator and induction coil, or a high tension Electric Machine, and a Hertzian Oscillator or Radiator, that is a pair of Electrodes, having an inductive action on one another, and designed to suddenly equilibriate opposite electric charges, impressed on them by an outside source (the induction coil or electric machine) by violent electric surgings preferably across a spark gap, or number of gaps thereby radiating energy into space. Any existing form of such Oscillator or Radiator may be used for the present purpose, as the three ball variety, consisting of one large central and two smaller charging balls, one on each side, but we prefer to use a modification of the form, designed by Professor Righi, wherein the spark is taken between a pair of balls, or electrodes, immersed in an insulating liquid, such as oil. In place of using balls for the Electrodes, however, we prefer to use more elongated rods with convex rounded, or half ball ends, as we find that the radiation from these is stronger than from balls & this form of electrode is useful whether immersed in liquid or not. We prefer however to incline these rods upwards or else to curve them upwards somewhat crescent-shaped, so that they may stand on insulating supports in a vessel of the insulating liquid, and their outer ends (that is those most distant from the pair of ends which oppose one another) project up out of the liquid, so that the charging sparks from the machine, or induction coil may more conveniently be impressed upon them. Our improved Radiator, constructed on this principle, is shewn in Fig. 1, wherein A A

are the elongated Electrodes, (the dotted lines indicating the optional straight form) B the vessel made of insulating material and containing the oil or other insulating liquid and C C the two small charging balls or Electrodes connected to the poles of the machine or induction coil secondary. It will be seen that this construction gives great facility for adjusting the spark gaps and is simple and the vessel not requiring any special shaping is not liable to leak and so release the liquid.

Similar letters are used to indicate all similar parts throughout the drawings.

We prefer to enclose the Radiator bodily in a metallic box, closed on all sides, but having an opening in front, the back of the box being preferably mirror-shaped or carrying a separate metallic mirror, and the front hole being either left open or preferably closed with a plate or lens of ebonite, pitch, or other suitable material to assist in rendering the rays approximately parallel, or of concentrating them into a beam.

To further render the beam parallel and cut off more of the diverging rays, so as to prevent them from operating other receivers out of their direct line, we may surround the front hole with a metallic pipe or tube, extending forward for any desired distance, and preferably having its front end closed with an insulating plate, or another lens, and having optionally other lenses in the course of its length. Fig. 2 is a side view of the exterior of the entire projector, shewing the focussing tube at E. The receiving instrument may also be enclosed in a similar box with tube.

The wires of the generating circuit or Oscillator may pass through suitably insulated holes in the back or other part of the metallic screen or projector box. The projector we place in such position as to project or concentrate as much as possible the beam or bundle of rays on to the Receiving Station. Or the Radiator may, in some cases, be used alone without any metallic projector-box and its outer charging knobs may be connected through condensers or otherwise to pipe systems or to earth, or one connected directly to earth and the other to an insulated surface, preferably elevated in the atmosphere. Or, and preferably, another separate pair of balls or knobs may be placed near the ends of the Electrodes A A as shewn at F F in Fig. 7, and these, instead of the charging knobs themselves, be connected via condensers or otherwise to pipe systems, to earth, or one directly to earth and the other to the elevated insulated surface. The second pair of balls are then preferably placed at such distance that they are not sparked into, together with each charging spark, passing from the charging knobs into the Electrodes A A, but a spark is precipitated into them by the more violent disruption occuring every time a spark passes across beween the Electrodes A A. This method has a great advantage in reducing leakage, but they may also be placed closer if preferred and charged together with the main electrodes.

In the battery, current generator, or primary circuit (where an induction coil is used) at the Transmitting Station we place a Morse or other Key convenient for signalling, so as to produce the waves intermittently in the form of dots and dashes. Or we may cause the signalling key, by means of a light long range arm or similar discharger, to open and close a short circuit across the secondary circuit of the induction coil, or of the poles or Electrodes of the high tension machine where such is employed for producing the charge, or to make and break the direct high tension circuit itself. A suitable construction for the key when used in this way is shewn in Fig. 3, wherein K is the Key, and L L Knobs communicating with the high tension electrodes. Or the key may operate a metallic screen, capable of covering part or all of the opening in front of the poles of the Oscillator, thereby alternately shielding and exposing the beam or pencil of rays from or on to the distant station, as shewn in Fig. 4, wherein M is the Key or operating handle, and N the screen.

At the Receiving Station for detecting the radiant energy we then provide a second oscillating circuit connecting inductive surfaces, or a road along which electric surgings can take place, or a metallic loop, open or closed, and in either case preferably syntonised as nearly as possible to the generating oscillating

circuit or radiator, and having in its path a "Lodge" Coherer, or set of loose contacts, or other light loose contact, through which a battery current is tending, the path of said battery current continuing on, either directly through the electric signalling instruments desired to be worked, or else through a relay or other similar instrument, capable of operating a local circuit in response to variations of resistance in the Coherer or set of loose contacts, produced by the varying impact of the Hertzian or Electric waves. A vibrator, operated mechanically or electrically, is also applied to the Coherer to continually restore its normal equilibrium or resistance after the latter has been changed by the impact of Electric waves.

We do not limit ourselves to any particular form of light contact for the Coherer but we prefer to employ a tube, made of glass, ebonite or other insulating material, shewn in Fig. 5 at O O, with stout conducting Electrodes, P P, sealed or otherwise fixed in, which Electrodes may terminate inside as either stout rods or tubes (shewn in the latter form at R R) extending near together, the remaining space in the tube being loosely filled with the conducting granules, or cohering contacts S and the air preferably exhausted to a very low tension, say through a small tubulure as T, the tube being then hermetically sealed.

The outwardly extending rods from the tube may have tubular conductors U U sliding on them and terminating in balls or other collecting or inductive surfaces. The object of the telescopic slides is to tune the receiver or adjust its rate to that of the Transmitting Oscillator when used for short distance work, or for longer distances the conductors may be connected to other extensions or circuit arrangements, or to pipe-systems, or to earth, or to insulated systems of collecting points placed at an adjustable distance apart, or one pole to such system and the other to earth, and for these connections, both from the Transmitting Radiator (or additional sparking knobs near same) and Receiving Coherer, we find broad strips far better than ordinary round wires, as possessing less self-induction and therefore offering far less impedance to the passage of the rapid electric surgings, or oscillating currents. The strips should be well insulated except when connected to earth.

Any metallic granules will answer, but we find the most effective consist of very fusible metals or alloys, the effect of cohering appearing to consist of a minute fusing together of the contact points or surfaces. For most signalling purposes, therefore, we prefer to use granules of soft solder, lead or tin, or alloys of lead and tin, with or without Bismuth or Cadmium or all together. For other purposes, however, we find Carbon granules very effective, especially when the Telephone is used as the receiving instrument as herein-after described.

V Fig. 5 shews the restoring vibrator consisting of an electro-magnet W and ordinary make and break contact X all enclosed in a tight metal box, Y, which may have extending tubes to enclose the battery wires. The armature pivot *x* extends through the box and carries the rod of a light tapper D, arranged to vibrate against the Coherer tube O. Or any other form of vibrator may be used and it may shake the Coherer in other ways without directly tapping it.

Another form of Receiver, which we sometimes use, is shewn at Fig. 6 and consists of the proper collectors and conductors E E formed of metallic strips or rods terminating in balls, or other suitable Electrodes, (the system being tunable for short distance working by bending the extremities more or less near together) or which strips or rods may be connected for longer distance working as above described with reference to the alternative granule tube, and the approaching ends being fixed to an insulating block G and bridged across by a very thin piece of wire H, preferably platinum or aluminium, bent tripod fashion, so as to rest lightly on three points, two being preferably on one Electrode and one on the other. The cohering contact surfaces and wire may also be covered by a suitably packed glass or other bell cover J, from which the air may be exhausted, as by a closable tube through the block G underneath, or otherwise. A vibrator V is also mounted preferably on the same base to restore the equilibrium. Fig. 7 is a diagram of connections of the complete set of Trans-

mitting and Receiving Apparatus, the electrical connections shewn in full lines being arranged for ordinary signalling and working, say, on a Morse Sounder or Printer. The connections shewn in dotted lines relate to another requirement to be described further on and should be ignored when considering plain Morse signalling only. In this figure the spirals lettered I represent the generating induction coil and *g* its make and break contact with preferably a condenser *h*. *a* represents the signalling Key at the Transmitting Station. A A, B and C C represent respectively the same parts as indicated by similar letters and described in reference to Fig. 1. F. F. are the pair of additional knobs for connecting respectively to elevated surfaces and to earth or to other arrangements as already described, and O O, P P, U U represent the receiving Coherer and V the vibrator as described in detail with reference to Fig. 5. *b* represents the relay and *c* the Morse Instrument, both of which may be of any ordinary form, and the latter either a Sounder or Printer. The shunt roads lettered *r* shewn across the Electro-magnets of the Morse Instrument and relay in Fig. 7 and of the Vibrator in Fig. 5 represent ordinary spark shunts or condensers which it is desirable to place across the Electro-magnets of all Instruments required in the vicinity of the receiving Coherer.

For certain purposes of signalling we also find it useful to produce the electric waves at the Transmitting Station in certain rated beats or series of impulses, so that, on the local circuit at the Receiving Station, being affected harmonically, in this rate, certain definite signals may be picked out and given from a series of possible signals operated by the same local circuit.

For this purpose we prefer to use the apparatus described in Patent Specification, No. 7773 of 1884, or other similar arrangements.

The Transmitting Pendulums or Reeds then take the place of or are used in conjunction with the Signalling Keys described above, at the Transmitting Station (operating as the Keys, but isochronously, to either open and close the electric circuit or to oscillate a screening shield) and the electro-magnetic Receiving Reeds or Pendulums being included in the local circuit at the Receiving Station, so as by their respective accumulation or interference to pick out and make the proper desired signals. A method of applying such synchronised vibrators, for both Transmitting and Receiving, is indicated by the dotted lines in Fig. 7, wherein on the transmitting side of the diagram *i* represents the transmitting pendulum or reed or its equivalent, the full line connection between the points *d* and *e* being now considered as broken, and the Key *a* being optional may be replaced by the direct connection *f*.

On the receiving side of the diagram *k k* represents in a typical form two of any number of the synchronised receiving pendulums or reeds (but of which any ordinary kind may be used) with their proper connections and *m* an electric bell or other signalling device arranged to be put into action locally by the synchronised vibrators.

As will be seen from the dotted connections the electro-magnetic coils of the synchronised vibrators now replace those of the Morse or other Telegraph Instrument which are now considered as absent, and a local current is applied to the bell or signal on the accumulation or effective operation of any of the synchronised vibrators, or the vibration of the latter alone (or of their equivalents) may also of course for some purposes suffice to make the signals.

This method of signalling is especially adapted and advantageous for Fire and Police Alarms and other Municipal Telegraphs, and is also useful for many other purposes.

For Telephoning we may place a Telephone Transmitter in the primary, or battery, or generator circuit at the Transmitting Station, either in place of or as a shunt for or in series with, the ordinary make and break *g* of the induction coil indicated at I Fig. 7, which make and break should then be rapid. Or (as shewn in Fig. 8) we may employ a moving shield *n* connected to a diaphragm and having a slit or slits to alternately expose more or less of the radiation emerging from a

similar slit or slits in a fixed metallic shield otherwise then completely, or nearly completely covering the front of the projector box *p*, containing the electrodes of the electric wave generating apparatus, so as to successively vary the intensity of the radiation in response and in proportion to sound waves thrown upon the diaphragm.

In both these cases it is desirable for the vibrating make and break in the primary circuit of the generating induction coil to be of high rate, and the transmitting oscillator circuit designed to give a considerable number of oscillations for each break, as, for instance, by connecting across by a loop of wire of some length the Electrodes A A of the transmitting radiator shewn in Fig. 1 or its equivalent, whereby it it less damped, although rendered less powerful, so that the received stream of energy shall be as continuous as possible, subject to the varying mechanism described above.

At the Receiving Station for reproducing or rendering the varying rays re-apparent as sound waves we may use any substance, or set of loose contacts, which will vary its, or their, electrical resistance, or resistances, in response to the impact of such radiation, (when properly collected and concentrated thereon, as herein-before described with reference to the Receiving arrangements for Telegraph Signalling) placed in the circuit of a Battery and suitable Telephone Receiver. This arrangement is shewn in Fig. 9 wherein *s* is the Coherer or tube containing loose contacts of the desired substance, and which Coherer may be constructed similarly to Fig. 5. This arrangement can also be used for receiving conventional signals, as produced by the operations of the Morse Key, depicted in Fig. 7 in the transmitting part of the apparatus. We find that a Telephone Receiver used in this way, in conjunction with a Coherer, having preferably but not necessarily, carbon granules, forms a very sensitive receiving set for detecting very weak radiant energy as when coming from a long distance *etc.*, because the Telephone is able to appreciate far more minute and temporary (but sudden) changes in the resistance of the Coherer than are required to vary a battery current sufficiently to operate any other telegraphic instrument. Used in this way also no restoring vibrator is required for the coherer, or at most only an arrangement to give a few momentary taps at long intervals, but this can be conveniently done by hand. Or instead of the Receiving Telephone being in direct circuit with the Coherer it may be connected across the secondary of an induction coil, whose primary is included in the battery and coherer circuit.

Having now particularly described and ascertained the nature of our said invention and in what manner the same is to be performed, We declare that what We claim is

1. A transmitting radiator of Electric energy, consisting of a pair of elongated rods, having their ends opposed to one another, and either inclined upwards at an angle, or else curved in a somewhat crescent shape, so that in either case the bulk of their surface, and especially their opposed ends, may be and are immersed in oil or other insulating liquids, contained in an electrically insulating vessel, while their opposite ends project out of said liquid conveniently for being charged by sparks sent across from knobs or Electrodes opposed thereto and connected to a source of high potential electricity, as and for the purposes above described.

2. A receiving Coherer, arranged as above described, advantageously for detecting electric radiation and consisting of a tube or vessel containing between or in contact with the Electrodes of the collecting conductors granules of very fusible metals or alloys as above enumerated and to accomplish the above-mentioned objects.

3. The use and employment for the purpose of confining a stream of electric radiation within narrow limits and so preventing it from operating other receivers not intended to be operated thereby, or for the purpose of picking out more closely and responding to the radiation coming from one better defined point only, a metallic tube extending out from the front and surrounding a hole in an otherwise

closed metallic box containing the radiation producing device or the radiation receiving device respectively, as and for the purposes above described.

4. Where an electro-magnetic vibrator is used to tap back or restore the normal equilibrium of resistance of a Coherer after its having been changed by electric radiation; the use and employment of a metallic box or case to cover in and enclose the said vibrator entirely with the exception of the projecting tapping hammer, or an axle on which this may be mounted, for the purpose of screening the radiation generated by the vibrator away from the receiving Coherer.

5. An electro-magnetic vibrator fulfilling the conditions mentioned in claim 3. above, and constructed as above described and illustrated in Fig. 5.

6. The use and employment in conjunction with an oscillator or radiator of electric energy of a second pair of knobs opposed to the main pair of Electrodes or surfaces, between which the oscillating currents or electric surgings are set up, and connected to pipe-systems, or earth, either with or without the interposition of condensers, or one to earth and the other to a radiating surface, preferably elevated in the atmosphere. Or the use of one separate knob, so connected, in conjunction with an earth connection or a connection to another of the above-mentioned systems, applied to the opposite charging knob.

7. The use and employment for the purpose of connecting the charging knobs or the surface of an Electric Radiator, or other knobs inductively opposed to them, to earth, or to other systems for increasing the radiation, of a conductor composed of a broad strip instead of a round wire, as heretofore used, as and for the purposes above described.

8. The combination with an induction coil or other high tension electric generator and an oscillator or radiator of electric energy, of Reeds or Pendulums for opening and closing the circuits of the induction coil or generator isochronously, or otherwise producing the rays intermittently, or of alternately exposing and shielding a beam of them, in an isochronous rate, for the purpose of actuating tuned or synchronous electro-magnetic Reeds or Pendulums, placed in the receiving circuit.

9. The combination with a Coherer, granule tube or loose contact system used for the purpose of detecting electric radiation of one or more synchronised electro-magnetic Reeds or Pendulums for the purpose of picking out a signal or one of a set of signals made by one transmitter without responding to others which may be acting simultaneously or successively, as and for the purposes above described.

10. The use and employment of a Telephonic Transmitter or Microphone in place of the ordinary make and break, or as a shunt for or in series with a rapidly vibrating make and break of the primary circuit of an induction coil used for producing Hertzian waves or high rate electric radiation capable of operating a receiver at a distance, as and for the purposes above described.

11. The means above described of varying the intensity of a very rapidly produced set, or nearly continuous stream of electric waves by means of a slotted screen covering and uncovering similar slots in a fixed screen in front of the electric projector, proportionately to sound waves thrown upon a diaphragm actuating such screen as and for the purposes above described.

12. The combination with a Coherer or set of loose contacts used for detecting electric radiation of a battery and telephone placed in the same circuit, whether the said telephone is used to re-produce speech or other sounds, or only conventional signals, as and for the purposes above described.

13. In a receiving set used for the purpose of reproducing signals or sounds from a varying stream of electric radiation, the combination of a Telephone, Induction coil, battery and Coherer, or set of loose contacts, the Telephone being connected to one coil, say the secondary, of the Induction coil and the other coil, say the primary, being connected in circuit with the Battery and Coherer or set of loose contacts.

14. Where a Telephone is used in conjunction with a Coherer or set of loose contacts and Battery as a receiving set for detecting and responding to variations of

electric radiation, the use and employment for the purpose of such Coherer or set of loose contacts of granules or subdivided particles composed of carbon.

15. The use and employment of a pointed conductor, or of a system of points projecting into the atmosphere and connecting to an apparatus for either transmitting or receiving electric waves.

Improvements in Instruments for Detecting Electric Oscillations.

other plate of this condenser with the sliding contact on the resistance across the glow lamp battery terminals. In this circuit I also include a telephone or current detecting instrument. A current then flows from the battery through the filament rendering it incandescent and also in virtue of the emission of negative electricity from the filament a current flows from it through the vacuous space to the metal cylinder and through the telephone or other current detector. The conductivity of this vacuous space or ionised rarefied gas is a function of the electromotive force acting to drive the current through it. I find that if the position of the sliding contact on the resistance across the terminals of the battery is so adjusted that corresponding thereto the conductivity curve of the ionised gas has a very sudden change in curvature, the superposition of an oscillatory potential difference between the filament and cylinder upon the steady potential difference causes very sudden changes in the current strength through the telephone and therefore an emission of sound.

The arrangement described is therefore a very sensitive detector of oscillations in the condenser circuit to which the glow lamp is attached and therefore can serve as an electric wave detector in inductive or radiotelegraphy, since the sound in the telephone or indication of the equivalent current detector can be controlled from the transmitting end and cut up into Morse or other signals as required, to transmit by electric waves or magneto electric induction intelligence to a distance.

PROVISIONAL SPECIFICATION.

No. 26,832, A.D. 1908.

"Improvements in Instruments for Detecting Electric Oscillations."

I, JOHN AMBROSE FLEMING, of University College, Gower Street, in the County of London, Doctor of Science, do hereby declare the nature of this invention to be as follows:—

My invention has reference to that type of electrical oscillation detector described by me in a British Patent Specification No. 24,850, of November 16th 1904, entitled "Improvements in instruments for detecting and measuring alternating electric currents."

According to this invention I employ a carbon cylinder as the cold conductor in the vacuous bulb in place of the metallic cylinders heretofore employed.

Dated this 10th day of December 1908.

J. A. FLEMING.

COMPLETE SPECIFICATION.

"Improvements in Instruments for Detecting Electric Oscillations."

I, JOHN AMBROSE FLEMING, of University College, Gower Street, in the County of London, Doctor of Science, do hereby declare the nature of this

invention and in what manner the same is to be performed to be particularly described and ascertained in and by the following statement:—

My invention has reference to that type of electrical oscillation detector described by me in a British Patent Specification No. 24,850 of November 16th 1904, entitled "Improvements in instruments for detecting and measuring alternating electric currents."

In this specification I described an oscillation detector subsequently called an oscillation valve or glow lamp detector, which consists of an electric glow lamp of the ordinary type, but having within the glass bulb a metal plate or cylinder carried on an insulated terminal sealed through the glass. When the filament is rendered incandescent by an electric current, it emits negative ions or corpuscles or electrons and these ionise the residual gas in the bulb, and give to the space a unilateral conductivity by which negative electricity can pass from the hot filament to the cold insulated plate or cylinder within the bulb, but not in the opposite direction. I employed this device as an electric wave detector in radiotelegraphy by connecting the insulated plate or cylinder to one terminal of an oscillation transformer inserted in the receiving circuit of the radiotelegraphic apparatus, and the other terminal of this oscillation transformer was connected through a galvanometer or telephone to the negative terminal of the filament.

I have discovered after many experiments that tungsten in various forms and particularly in a form in which it is employed as the filament in a glow lamp is highly efficient for this purpose, since the amount of negative electricity emitted at the highest possible working temperature may be from 10 to 20 times as great as that emitted by carbon in an ordinary carbon filament. I am unable to explain the reason of this superiority; it is not merely that a tungsten filament can be raised to a higher temperature than a carbon filament, for metals such as tantalum which are closely analogous to tungsten and which can be raised to an equally high temperature are not much superior to carbon at any temperature at which they can be worked in practice.

I find that a cylinder of carbon acts better as the cold conductor in the bulb than a metallic cylinder.

I construct such a metallic or semi-metallic filament glow lamp with a tubular glass bulb and a cylinder of carbon sealed into the bulb, surrounding but not touching the filament, and connected to a platinum wire sealed through the glass. Furthermore, I employ this glow lamp as an oscillation detector as follows:—The filament is rendered incandescent by an insulated battery having in series with it a rheostat or variable resistance for controlling the current. Across the terminals of this battery I place another high resistance having a sliding contact in it, so as to make contact with any desired point on this resistance. In using this detector in wireless telegraphy the receiving circuit must comprise a closed circuit having inductance and containing a condenser. If the telegraphy is conducted by electric waves it is necessary also to connect an antenna either directly or indirectly with this condenser circuit. I then connect the insulated cylinder included within the bulb of the lamp with one plate of the condenser in the oscillation circuit, and I connect the other plate of this condenser with the sliding contact on the resistance across the glow lamp battery terminals. In this circuit I also include a telephone or current detecting instrument. A current then flows from the battery through the filament rendering it incandescent, and also in virtue of the emission of negative electricity from the filament a current flows from it through the vacuous space to the metal cylinder and through the telephone or other current detector. The conductivity of this vacuous space or ionised rarefied gas is a function of the electromotive force acting to drive the current through it. I find that if the position of the sliding contact on the resistance across the terminals of the battery is so adjusted that corresponding thereto the conductivity curve of

3176

the ionised gas has a very sudden change in curvature, the superposition of an oscillatory potential difference between the filament and cylinder upon the steady potential difference causes very sudden changes in the current strength through the telephone and therefore an emission of sound provided that the steady potential difference is of the necessary critical value.

The arrangement described is therefore a very sensitive detector of oscillations in the condenser circuit to which the glow lamp is attached and therefore can serve as an electric wave detector in inductive or radiotelegraphy, since the sound in the telephone or indication of the equivalent current detector can be controlled from the transmitting end and cut up into Morse or other signals as required, to transmit by electric waves or magneto electric induction intelligence to a distance.

In carrying my invention into effect, I employ a tubular form of glass bulb *a* which may be an inch or more in diameter and 5 or 6 inches in length. In this I insert a cylinder *b* of carbon which is sprung into the glass tube so as to fit the walls tightly. This cylinder has a platinum wire *c* twisted or welded to it which is sealed through the glass, so as to make an external electrical connection. The bulb *a* should have a good vacuum such as is usually employed with lamps having metallic filaments.

The metallic filament *d* is formed of tungsten in the form used as a filament in ordinary glow lamps and is connected to conductors *e* carried on a glass tubular stem *f* sealed into the bulb. The filament *d* should be of such a length that it is entirely covered by the metal cylinder *b*.

It is convenient to have the filament of such length and thickness that the voltage required to bring it to incandescence at which its duration may not be less than several hundred hours, is of the order of 18 volts or so.

In applying this glow lamp as a detector in radiotelegraphy I arrange it as follows:—

A battery *g* of secondary cells is provided which may conveniently be a dozen or more cells, and wires *h* are brought from the terminals of this battery to the terminals *e* of the filament of the lamp, a variable resistance *j k* being inserted in the circuit. It is convenient to divide this resistance into two, one namely *j* of from say 0 to 120 ohms being for coarse adjustment and the other *k* of from say 0 to 5 ohms being for fine adjustment. By means of these resistances the current of the lamp may be adjusted to have any required value. A voltmeter *l* should also be placed across the terminals of the filament to regulate the voltage. In addition I place across the terminals of the battery *g* a high resistance *m* of the potentiometer type, that is to say, a resistance which may be two or three hundred ohms or more, the terminals of which are connected to the terminals *h* of the battery. A double high resistance telephone *n* (the resistance of each telephone being at least five or six hundred ohms) has one terminal connected to a slider *o* which can make contact with any required point on the resistance *m* and the other terminal connected to one plate of a condenser *p*. The other plate of the condenser *p* is connected with the metal cylinder or the lamp. The condenser *p* is inserted in a circuit possessing inductance, which is directly or inductively connected with a receiving antenna. As shown the circuit connecting the two plates of the condenser *p* contains an adjustable inductance *q* and the secondary of the jigger *r* the primary of which is in the aerial *s*. When electric waves fall upon the receiving antenna they excite oscillations in the condenser circuit and oscillations are thus imposed upon the telephone circuit connecting the metal cylinder or plate in the lamp with the sliding contact and high resistance connected across the terminals of the battery or other source of continuous electric current.

In operating the arrangement, the first step is to bring the filament to a high incandescence at which it would be working approximately at one watt per candle and at which it will have such a temperature, approximately 2800° C.

2758

that it will diffuse into the vacuous space negative ions discharged from the incandescent filament.

The filament having been rendered incandescent to this temperature, the observer applies the telephone to his ear and if electric wave trains are falling upon the receiving antenna *s*, it will be found that on moving the slider *o* along the potentiometer resistance *m* from one end to the other, there is a certain point at which sounds will be heard in the telephone better than at any other point. The exact position of the slider *o* must be determined by trial for it varies with every valve owing to slight differences in the vacuum and temperature of the filament. The detector above described is suitable as the receiver in radiotelephony, as well as for signals on the Morse or other alphabetic code.

Having now particularly described and ascertained the nature of my said invention and in what manner the same is to be performed, I declare that what I claim is:—

1. An oscillation valve in which the hot conductor is a filament of tungsten substantially as described.

2. An oscillation valve in which the hot conductor is a filament of tungsten and the cold conductor is a cylinder of carbon substantially as described.

3. The combination of an oscillation valve, a source of electricity heating the filament of the valve, a resistance across the terminals of the source, a circuit connected at one end to the cold conductor of the valve and at the other to an adjustable point of the resistance, and means for producing oscillations and detecting electric current in the circuit substantially as described.

4. Instruments for detecting electric oscillations substantially as described and illustrated in the drawing.

Dated this 10th day of December 1908.

UNITED STATES PATENT OFFICE.

GUGLIELMO MARCONI, OF LONDON, ENGLAND, ASSIGNOR TO MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA, OF NEW YORK, N. Y., A CORPORATION OF NEW JERSEY.

RECEIVER FOR WIRELESS TELEGRAPHY.

No. 896,130. Specification of Letters Patent. Patented Aug. 18, 1908.

Application filed March 13, 1907. Serial No. 362,121.

To all whom it may concern:

Be it known that I, GUGLIELMO MARCONI, LL. D., D. Sc., a subject of the King of Italy, residing at 18 Finch Lane, in the city of London, England, have invented new and useful Improvements in Receivers for Wireless Telegraphy, of which the following is a specification.

This invention relates to a method of employing the well known Fleming's oscillation valve (described in the U. S. A. specification No. 803,684) in wireless telegraphy. This valve consists of a vacuous vessel having in it two conductors adjacent to but not touching each other one conductor being heated in any convenient manner while the other is connected to an external circuit.

The oscillation valve is preferably placed in shunt with the secondary of the step-up transformer or jigger which is, as usual, connected with the aerial. The circuit including the secondary coil of the jigger and the oscillation valve, also includes the primary or fine wire winding of the induction coil or step-down transformer, the secondary winding of which is connected with a telephone receiver, relay, or other suitable wave responsive device for detecting the received signals.

A condenser may be placed in series between the valve and the induction coil and a second condenser in a shunt across the ends of the secondary of the jigger.

The condenser last mentioned together with the secondary winding of the jigger forms a closed oscillatory circuit when the capacity of this condenser is properly adjusted for syntonism.

The values of the inductance and capacity of the transformer or jigger and the value of the capacities of the condensers associated to it should be such as to bring the receiving circuit, including said jigger into resonance with the period of the transmitted oscillations.

The drawing is a diagram of the arrangement it is preferred to adopt.

a is a glass bulb, and *b* is a carbon filament like the carbon filament of an incandescent lamp, suitable say for taking a current of 6 to 8 volts and 2 to 4 amperes. *c* is a cylinder of aluminium opened at the top and bottom which surrounds but does not touch the filament. The cylinder *c* is supported and steadied by platinum wires *d*, and the ends of the filament *b* are connected to platinum wires connected to the leads *e* and *f*. The platinum wires are sealed through the glass in the ordinary manner. *h* is a battery by which the filament *b* is heated. This arrangement is one form of the oscillation valve described in the said former specification.

One of the wires *d* is connected to the secondary *j* of the jigger the primary *k* of which is connected to the ordinary aerial *l* and to earth. The other end of the secondary *j* is connected by a wire *m* to one end of the fine wire winding of an induction coil *n* (which should be such as usually manufactured to give say a 10 inch spark) the other end of its fine wire winding being connected by a wire *o* through a condenser *p* to the lead *e*. When the induction coil is thus connected, the fine wire winding, usually operating as a secondary winding, becomes the primary coil, while the course wire winding, usually operating as the primary winding, becomes the secondary coil. The ends of the secondary of the coil *n* are connected to a circuit *q* containing a detector *s* of any ordinary type such as a telephone or a relay operating a printing instrument. *t* is a condenser in a shunt across the secondary *j* of the jigger.

By using a condenser, such as the condenser *t*, in the resonant circuit, the receiving circuit not only may be more easily brought into syntonism with the received oscillations, but such condenser permits the oscillations in the resonant circuit to accumulate to such an extent that their electromotive force is sufficient to overcome the resistance of the space between the filament *b* and the cylinder *c* in the oscillation valve, thereby increasing the strength of the waves rectified by said valve. Inasmuch as the electromotive force of the oscillations rectified by the oscillation valve is high, while its current value is small, the induction coil *n* transforms the current so that it acts upon the detecting device as one of lower potential and higher current value. These conditions are, therefore, the reverse of those usually found in detectors for electromagnetic waves heretofore used.

Inasmuch as the fine wire winding of the inductance coil *n* introduces a large amount of inductance into the receiving circuit, the condenser *p* is introduced to counteract the same.

The pulsating current produced in the

parts of the receiving circuit comprising the filament *f* the wire *e*, the wire *o*, the condenser *p* the fine wire winding of the induction coil *r*, and the wire *m*, results in an alternating current in the wires *q* and the detector *s*, the latter current being of comparatively large volume and low potential.

The term "aerial" is intended to embrace any conductor in which oscillations are set up by the incoming Hertzian waves.

What I claim is:

1. In a receiving apparatus for wireless telegraphy, the combination with an oscillatory circuit, of an oscillation valve, an induction coil, the oscillation valve and the primary winding of the induction coil being connected in series and operatively connected with said oscillatory circuit, and a detecting device connected with the secondary winding of said induction coil.

2. In a receiving apparatus for wireless telegraphy, the combination with an oscillatory circuit including a condenser, of an oscillation valve, an induction coil, the oscillation valve and the primary winding of the induction coil being connected in series with each other but in shunt with said condenser, and a detecting device connected with the secondary winding of said induction coil.

3. In a receiving apparatus for wireless telegraphy, the combination with an oscillatory circuit, of an oscillation valve, an induction coil and a condenser, said valve, condenser and the primary winding of the induction coil being connected in series and operatively connected with said oscillatory circuit, and a detecting device connected with the secondary winding of said induction coil.

PLAINTIFF'S EXHIBIT 290

The same considerations apply to the mutual conductance which can be taken approximately to be equal to the slope of the line joining the extreme point of the characteristic over which the operation takes place.[1]

The problem of setting up the conditions for oscillation, therefore, reduces to the solution of a network involving the oscillation circuit, LCr, a fictitious generator giving a voltage equal to μe_g and a resistance r_p, as defined above. By adopting this procedure, we do not entirely ignore the curvature of the characteristic. If the resistance r_p were not dependent on the intensity

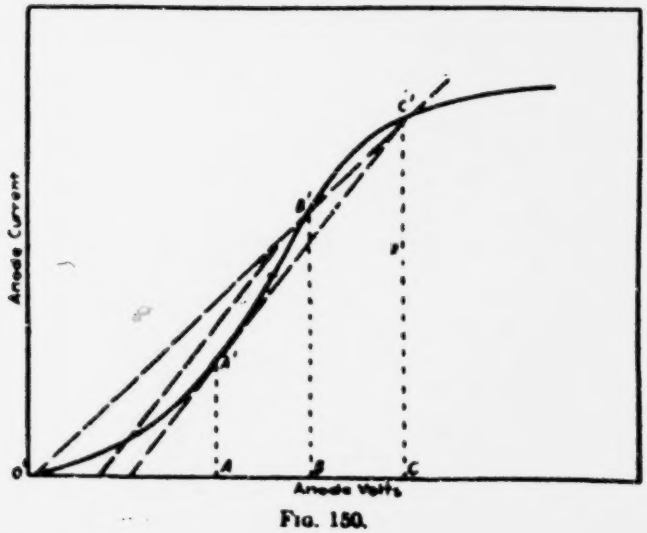

FIG. 150.

of the oscillations, the solution of the network involving the quantities enumerated above would not give an indication of the amplitude of the oscillations; however, both r_p and the mutual conductance g_m are dependent on the intensity of the oscillations. The condition for oscillation will require that r_p and g_m have values lying within certain limits, and since their values depend on the extent of the characteristic over which operation takes place, the amplitude of the oscillations will be determined by the shape of the characteristic and the constants of the external circuit.

81. Conditions for Oscillation in a Two-element Device. Let us first consider the simple case of a device containing two

[1] L. A. HAZELTINE, Proc. I.R.E., Vol. 6, p. 63, 1918.

2764

Claimant's Exhibit No. 290

electrodes and having a resistance r, and see what are the conditions that must be satisfied in order that this device, when connected to an oscillation circuit may produce sustained oscillations. The circuit is shown diagrammatically in Fig. 151. The device is supplied with a direct current by means of the battery E, through the choke coil Ch. The oscillation circuit is represented by LC.

The condition for oscillation in such a circuit can be obtained by the simple process of setting the differential equation for the circuit and equating the damping factor to zero. In doing so we need, of course, only to consider the a-c. circuits, that is, the

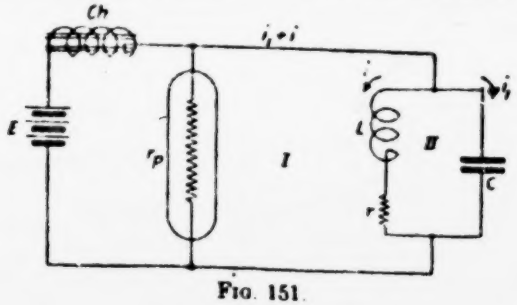

FIG. 151.

two branches I and II. Thus, summing the electromotive forces for circuit I, we get

$$r_p(i_1+i)+ri+Lpi=0, \quad \ldots\ldots\ldots \quad (1)$$

where $p=\frac{d}{dt}$

For branch II we have

$$Lp^2i+rpi=\frac{i_1}{C} \quad \ldots\ldots\ldots \quad (2)$$

Putting the value of i_1 given by equation (1) into (2) we get:

$$p^2i+\left(\frac{r}{L}+\frac{1}{Cr_p}\right)pi+\frac{i}{LC}\left(1+\frac{r}{r_p}\right)=0. \quad \ldots \quad (3)$$

This is an equation of the well-known form from which it follows directly that in order that the current i shall be oscillatory, the coefficient of the linear term must be zero. That is:

$$r_p=-\frac{L}{Cr} \quad \ldots\ldots\ldots \quad (4)$$

2765

From this we see that in order to obtain sustained oscillations from a device having only two electrodes, it is necessary that the device shall have a negative resistance. Examples of negative resistances have already been given in the previous pages. Thus an arc may have a negative resistance, its characteristic being of the form shown by the curve AB in Fig. 34. The resistance is given by the slope of the characteristic and this is a negative quantity for a characteristic of the kind shown. Fig. 16, page 48, shows another characteristic which over a region ABC has a negative slope and is obtained as the result of the emission of electrons from metals under the impact of electrons. Such characteristics as these are sometimes referred to as "falling characteristics."

The thermionic valve does not show a falling characteristic like the curve AB of Fig. 34, when it is sufficiently well evacuated to prevent the effects of ionization by collision from appreciably influencing the discharge. The characteristics of thermionic valves are those given and discussed in the previous chapters and it will be seen that for such devices the resistance is always positive. It is, therefore, impossible to obtain sustained oscillations from a well-evacuated thermionic valve containing only two electrodes. If such a device contains an appreciable amount of gas during the operation, the characteristic becomes unsteady and sometimes, especially at the higher voltages, exhibits regions over which the slope is negative, and when operated over that region it is, of course, possible to obtain sustained oscillations. The condition which makes this possible in a two-electrode device is unfortunately due to the cause which makes such a device unsatisfactory; namely, the presence of too much gas in the device, thus causing unsteadiness of the discharge and making reproducibility practically impossible. If a controlling electrode or grid be added to the two electrodes of a valve, the operation becomes different and we now have a device which can produce sustained oscillations with facility while at the same time satisfying all the conditions that are necessary to secure satisfactory operation in every respect, namely, freedom of gas with consequent steadiness and reproducibility of results, and comparatively long life.

82. Condition for Oscillation for Three-Electrode Tube. Let us now consider a circuit like that shown in Fig. 152. This is one of a large number of possible oscillation circuits. It is

distinct from the electrode A in the Fleming valve), the relay circuit being joined to this electrode and to the filament in series with a considerable pressure (15 to 20 volts). When electrical oscillations pass between the A electrode and the filament there is a marked alteration in the current flowing between the B electrode and the filament. This alteration is found to be so marked that it can be used for relay purposes, the relay consisting of two or more audions in series with transformers between them, current from the B electrode of the first being supplied to the primary of a transformer whose secondary supplies oscillations to the A electrode of the second, and so on. By this means an amplification of 120 times has been obtained by using three audions in cascade, and the current thus becomes sufficiently large to operate a moderately sensitive contact relay which, in its turn, can be used to operate a calling device; or the audion may be used with its amplified current in connection with a telegraphone. The latter seems to give promise of interesting developments as it provides a simple means of recording. For this purpose it has been used at the new stations of the Federal Telegraph Company, recording messages between San Francisco and Los Angeles, but it is not limited to new stations. Further, there are possibilities that the instrument may be used as a telephone relay. In passing we must confess we have no affection for the name "audion," to which exception was taken at the time it was introduced, and we think that Dr. DE FOREST might be more generous in his acknowledgment of the work by Dr. J. A. FLEMING. Our readers generally will probably agree that the audion, although differing widely from the Fleming valve, is an offshoot of it.

The Status of the Engineer.

In his inaugural address to the Dublin Local Section of the Institution of Electrical Engineers last week, Mr. G. MARSHALL HARMONY gave some interesting details of the way in which the medical profession many years ago raised the status of its members and excluded undesirables from its ranks. The obvious deduction is that electrical engineers should go and do likewise. Now, it cannot be denied that at the present time the electrical profession and industry are much too loosely organized. It nominally contains within its ranks many who are not engineers at all, and many whose lack of what is right and proper brings discredit on the body as a whole. And though we wish that this state of things might be changed, we feel that what the medical men did in 1858 cannot be taken as a precedent or as an example which electrical engineers may profitably follow. The medical profession adopted a course which was the best for them, but we do not think it would necessarily be the best for electrical engineers. There are two reasons for this. In the first place, engineering, especially electrical engineering, is divided against itself, with the result that it would be almost impossible at the present time to draft a Bill similar to that of the Medical Act of 1858 on lines with which even a majority of those engaged in electrical work would agree. This statement must not be taken as reflecting on either class; it simply implies that the professions and trade, and even separate branches of [illegible] impossible to reconcile them. Another and [illegible] is that caused by the conditions under which [illegible] electrical engineering work is carried on. Indeed, it is [illegible] difficulty which prevents an almost insuperable [illegible] to electrical engineers following the example of the [illegible] profession.

In the medical profession a [illegible] either [illegible] qualified man or he is not. Moreover, the profession is a homogeneous body. It is, therefore, easy to draw a hard-and-fast line, and to say that those who are on one side of this line are professionally equal and those who are on the other side are nowhere. This, however, cannot be done with electrical engineering as a whole owing to the presence of a numerous rank and file. Moreover, in this army, commissioned and non-commissioned officers are often very closely connected, those in one class merging very nearly into those of the other, so that, while it is possible to take one man and say here is a fully qualified engineer, and to take another and say here is a fully unqualified engineer, there are many others whose status is notwithstanding, [illegible] such that a division between those on one side the line and those on the other is indeterminate. This being so, it is difficult to see how anybody connected with electrical engineering can be prevented from calling himself an electrical engineer, though, as BARRY PAIN says, "to be an electrical engineer is another matter."

The question is, therefore, a very difficult one, for though it is possible to regulate matters among the [illegible] class, as is being successfully done by the Association of Consulting Engineers, the same procedure cannot be followed throughout the trade where a man's status cannot be definitely defined. It may be urged that trade unions do what we say cannot be done; but it should be pointed out that, after all, they [illegible] single class, and in our view often impose restrictions which are not for the public good. But even if this contention were correct it would not affect our argument, because neither legislation nor consulting engineers can [illegible] somehow that very large middle class which prides itself at the present time most requires enlightenment. And it is here to [illegible] that legislation must fail, for a while at least, to be effective. It rather requires that every man should perform his own work in accordance with the highest principles, and with the purest ethical aim, so that electrical engineering may be cleansed from within and the charlatan quelled.

Sun Power.—An interesting [illegible] of the [illegible] power plant was shown this week at the Shaftesbury Pavilion. This plant has been laid down in Egypt for irrigation purposes, and consists of five long semi-cylindrical mirrors, which concentrate the rays of the sun on a small iron boiler in the focus of a pipe running along the axis of the cylinder. The mirrors are automatically turned by a thermostat to catch the sun's rays to the maximum extent. This plant is capable of supplying 1,000 lb. of steam per hour. [illegible] the Empire there is said to be a great saving with this type of plant. The mirrors are 330 ft. long and are spaced 20 ft. apart. It is estimated that 220 H.P. can be obtained for every acre of ground covered with mirrors.

UNITED STATES PATENT OFFICE. 3201

LEE DE FOREST, OF NEW YORK, N. Y.

OSCILLATION-RESPONSIVE DEVICE.

No. 824,637. Specification of Letters Patent. Patented June 26, 1906.

Application filed January 18, 1906. Serial No. 296,615.

To all whom it may concern:

Be it known that I, LEE DE FOREST, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented a new and useful Improvement in Oscillation-Responsive Devices, of which the following is a specification.

My invention relates to devices for detecting feeble electrical currents or oscillations in general, and especially such currents or oscillations which are developed in wireless-telegraph receiving systems.

The object of my invention is to provide an oscillation detector or responder of great simplicity and sensitiveness and one which, inasmuch as it does not depend for its operation upon any variation of resistance of an imperfect electrical contact or any variation of the apparent resistance or counter electromotive force of a polarization-cell, requires no adjustment when employed for receiving wireless-telegraph signals.

With these objects in view my invention comprises a receptacle inclosing a sensitive gaseous conducting medium, the conductivity of which does not necessarily depend upon the heat of combustion, although such conductivity may be increased by heating said gaseous medium, and which in some cases requires practically no heating at all, a wave-intercepting means associated with said gaseous conducting medium, whereby the feeble electrical currents or oscillations resulting from the energy absorbed from electromagnetic signal waves may be impressed upon said gaseous conducting medium to alter its conductivity, and a signal-indicating device operatively connected with said gaseous conducting medium, whereby alterations in the conductivity of the latter may be made manifest.

My invention may best be understood by having reference to the drawings which accompany and form a part of this specification and which illustrate diagrammatically several simple and effective means whereby my invention may be practiced.

In the drawings, Figures 1, 2, 3, 4, 5, and 6 represent wireless-telegraph receiving systems provided with various forms of the oscillation responsive device which forms the subject-matter of the present invention.

In each figure, A represents a receiving antenna connected to earth at E and associated with the receptacle B. In Figs. 1, 3, 4, 5, and 6 the sensitive gaseous conducting medium inclosed in said receptacle is shown interposed between the antennæ and their earth connections, while in Fig. 2 said medium is shown interposed between the terminals of the tuned receiving-circuit *i C G i H*, which is inductively associated, by means of the autotransformer H, with the antenna A. By means of the four adjustable contacts *i* said tuned receiving-circuit and antenna may each be attuned to the frequency of the waves to be received. My invention, however, is not limited to any particular wireless-telegraph system, nor is it limited to wireless telegraphy, for it may be employed as a detector of feeble electrical impulses however produced.

I have discovered that the gaseous medium intervening between two separated electrodes if put into a condition of molecular activity will become highly sensitive to electrical oscillations, so that the passage across such medium of said oscillations will alter the conductivity thereof, and thereby create current variations in a circuit including said electrodes. The means which may be employed for putting said gaseous medium into a condition of molecular activity may consist of means whereby the medium is heated either by radiation, conduction, or by the actual combustion of gases. An electric current from any suitable source may be employed to heat two highly-resistant electrodes, and thereby to heat the gas intervening between said electrodes without having recourse to the heat of combustion. Said gas may be air, or the electrodes may be inclosed and surrounded by any suitable gas. The heating of the gas may also be affected by radiation from said electrodes. In fact, in the invention disclosed in the present application any suitable means for producing a heated gas with properly dissociated and conducting ions may be employed.

In all the embodiments of the present invention the electrodes are inclosed and are surrounded by suitable gas, and they may be inclosed in a receptacle which may be partially exhausted. Said gas may be rendered sensitive to electrical oscillations by slightly heating the same, preferably by electrical means, or by any other suitable means; but in those embodiments of my invention shown in Figs. 4, 5, and 6 practically no heating at all is required, while if in place of the potassium or other salt hereinafter described as

suitable for use in Fig. 6 some radio-active substance, such as radium bromid, be employed absolutely no heating is necessary.

In Fig. 1 two filaments C, which may be ordinary incandescent-lamp carbon filaments, are sealed into the receptacle B and each is connected to a separate battery D. The local-circuit battery H and telephone F connect said filaments C. One filament is connected with the antenna A and the other is connected to earth E, although the said filaments may be associated with the antenna in any manner in which existing wireless-telegraph receivers are associated with their receiving antennæ. In lieu of connecting the telephone F in series with the local-circuit battery H said telephone may be connected in shunt to the circuit including the filaments C, which form the electrodes of the oscillation responsive device, and local battery H, as shown in Fig. 2, and such arrangement of telephone-receiver may be employed, if desired, in those embodiments of the present invention which are shown in Figs. 3 to 6, inclusive.

The potential to be impressed upon the electrodes C by the battery H depends upon the nature of the gas intervening between said electrodes and upon the degree of exhaustion maintained within the receptacle B. I have found that from twenty-five to one hundred and ten volts is sufficient, and by employing a higher degree of exhaustion a much smaller voltage may be used. The conductivity of the gas, which may be air or a gas containing compounds of the halogens or halogen salts or which may be mercury vapor, is increased by the heat resulting from the passage of the current from the batteries D through the filaments C, and a leak-current of relatively small value continually flows in the circuit containing the battery H and the electrodes C across the gap intervening between said electrodes. The passage of electrical oscillations across said gap alters the conductivity of the gas in said gap, probably by changing the speed of the ions in said gas, and thereby current variations are produced in the circuit containing the battery H, the electrodes C, and the telephone F, causing said telephone to respond. When the telephone is in series with the battery H and electrodes C, the passage of oscillations across the gap between the electrodes causes an increase of current through the telephone, and when the telephone is in shunt to said electrodes, as shown in Fig. 2, the passage of oscillations across the gap causes a diminution of current through the telephone.

It is not necessary to employ two heated electrodes in carrying out my invention, for, as shown in Fig. 3, one electrode may be replaced by a conductor I, herein shown as a disk, of platinum or other suitable material. In this case the conductivity of the gaseous medium between the two electrodes I and C is sufficiently increased to render the same sensitive to the electrical oscillations by the radiation of heat from the electrode C.

In that embodiment of my invention shown in Fig. 4 I dispense with both heated electrodes C and substitute therefor two electrodes I, of platinum or other material, and connect the same in circuit with the battery H and telephone F. In Fig. 4 the telephone F may be connected in shunt to the battery-circuit in the manner shown in Fig. 2 of the present case.

In Fig. 5, L represents a source of alternating electromotive force of a frequency so high that a high-pitch note is constantly heard in the telephone F or else so high as to exceed the limit of response of the telephone-diaphragm. The advantage in using the source of alternating electromotive force is that the voltage may be stepped up by a transformer M to any desired amount—for example, from fifty to one thousand volts—and impressed upon the electrodes I. In lieu of an alternating-current generator such as shown in Fig. 5 any source of vibratory electromotive force may be employed. The telephone F may be included in series with the circuit containing the secondary of the transformer M and electrodes I, or it may be connected in shunt to said circuit, as above stated in connection with Fig. 2, and the effect of the passage of high-frequency oscillations across the gap between the electrodes I may be increased in the telephone by including a battery J in series with the telephone. In such case the conductivity of the gas in said gap effected by the high-potential alternating current will allow the relatively low potential direct current from the battery J to flow in the circuit containing the telephone and the electrodes, and the passage of electrical oscillations across the gap between the electrodes will produce sudden changes in the conductivity of said gas, and therefore in the amplitude of the current flowing in the telephone-circuit.

A convenient way of producing a gaseous medium containing compounds of suitable salts is shown in Fig. 6, in which a globule of a solution of some such salt is placed in the bottom of a vessel O, as shown at Q, and a heating-coil P is associated with said globule in such a way that the current from the battery K will heat said coil and create a heated gas of said salt in the globe O. I prefer to employ potassium hydrate as the salt to be heated, and better effects may be obtained by inclosing the globe O inside the evacuated globe B to prevent the radiation of heat from the inner globe. The heated gas from the potassium or other salt fills the globe O, which may be exhausted to any desired degree, and completes the circuit of the battery J

and telephone F, which is connected to two electrodes, of platinum or other suitable material, in the globe O. The passage of electrical oscillations across the gap between said electrodes will alter the conductivity of the aforesaid heated gas, and thereby create current variations in the circuit of the telephone F.

All the foregoing apparatus comprises means for sensitizing the interelectrode medium, as suitable salts impregnating the said medium, as before noted, or means for producing and maintaining the medium in a state of molecular activity, as by heating, or both means for sensitizing may be concurrently employed.

I do not wish to be limited to the particular embodiments of my invention which I have herein disclosed, inasmuch as many modifications may be made therein by those skilled in the art without departing from the spirit of my invention.

I claim —

1. An oscillation-responsive device comprising a receptacle inclosing a sensitive gaseous conducting medium containing a halogen salt.

2. An oscillation-responsive device comprising a receptacle inclosing a sensitive gaseous conducting medium containing a halogen salt and means for heating said medium.

3. An oscillation-responsive device comprising a receptacle inclosing a sensitive gaseous conducting medium containing a potassium salt.

4. An oscillation-responsive device comprising a receptacle inclosing a sensitive gaseous conducting medium containing a potassium salt and means for heating said medium.

5. An oscillation-responsive device comprising a receptacle inclosing a sensitive gaseous conducting medium containing a halogen salt and means for putting said medium in a condition of molecular activity.

6. An oscillation-responsive device comprising a receptacle inclosing a sensitive gaseous conducting medium containing a potassium salt and means for putting said medium in a condition of molecular activity.

7. An oscillation-responsive device comprising a partially-exhausted receptacle, two separated electrodes sealed in said receptacle and each forming part of a separate electric circuit, a separate source of electric current for each said circuit, and means whereby electrical oscillations may be impressed upon the gaseous medium intervening between said electrodes.

8. An oscillation-responsive device comprising a partially-exhausted receptacle containing two separated electrodes, a source of electromotive force associated with said electrodes, and means whereby a relatively small electric current is caused to flow normally in the circuit including said source of electromotive force, said electrodes and the gaseous medium intervening between the latter.

9. An oscillation-responsive device comprising a partially-exhausted receptacle containing two separated electrodes, a source of electromotive force associated with said electrodes, and electrical means for heating said electrodes whereby a relatively small electric current is caused to flow normally in the circuit including said source of electromotive force, said electrodes and the gaseous medium intervening between the latter.

10. An oscillation-responsive device comprising a receptacle, two separated electrodes inclosed within said receptacle and each forming part of a separate electric circuit, a source of electric current associated with each said circuit, and means whereby electrical oscillations may be impressed upon the gaseous medium intervening between said electrodes.

11. An oscillation-responsive device comprising a receptacle inclosing a gaseous medium containing a substance the vapor of which is conducting, and electrical means for heating said medium.

12. An oscillation-responsive device comprising a receptacle inclosing a gaseous medium containing a halogen salt, two separated electrodes inclosed within said receptacle, and a source of electric current so associated with said electrodes as to render said gaseous medium sensitive to electrical oscillations.

In testimony whereof I have hereunto subscribed my name this 13th day of January, 1906.

LEE DE FOREST.

UNITED STATES PATENT OFFICE.

LEE DE FOREST, OF NEW YORK, N. Y.

OSCILLATION-RESPONSIVE DEVICE.

No. 836,070. Specification of Letters Patent. Patented Nov. 13, 1906.

Original application filed January 18, 1906. Serial No. 296,615. Divided and this application filed May 19, 1906. Serial No. 317,721.

To all whom it may concern:

Be it known that I, LEE DE FOREST, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented a new and useful Improvement in Oscillating Responsive Devices, of which the following is a specification.

My invention relates to devices for detecting feeble electrical currents or oscillations, in general, and especially such currents or oscillations which are developed in wireless-telegraph-receiving systems.

The object of my invention is to provide an oscillation detector or responder of great simplicity and sensitiveness and one which inasmuch as it does not depend for its operation upon any variation of resistance of an imperfect electrical contact or any variation of the apparent resistance or counter electromotive force of a polarization-cell, requires no adjustment when employed for receiving wireless-telegraph signals.

With these objects in view, my invention comprises a receptacle inclosing a sensitive, gaseous conducting medium; a wave-intercepting means associated with said gaseous conducting medium whereby the feeble electrical currents or oscillations resulting from the energy absorbed from electromagnetic signal-waves may be impressed upon said gaseous conducting medium to alter its conductivity; and a signal-indicating device operatively connected with said gaseous conducting medium whereby alterations in the conductivity of the latter may be made manifest.

My invention may best be understood by having reference to the drawing which accompanies and forms a part of this specification and which illustrates diagrammatically one embodiment of my invention.

In the drawing, the figure represents a wireless-telegraph-receiving system provided with one form of the oscillation responsive device which constitutes the subject-matter of the present invention.

In the figure, A represents a receiving-antenna connected to earth at E and associated with the receptacle B. Two electrodes C and I are inclosed within said receptacle, which may be partially exhausted, and, as shown, they are sealed in said receptacle. The electrode C may be an ordinary incandescent-lamp-carbon filament, which is connected with a battery or other source of electrical energy D. The electrode I may be any suitable conductor and is herein shown as a disk of platinum or other material. The gaseous medium inclosed between the electrodes C and I is rendered sensitive to electrical oscillations by the radiation of heat from the electrode C, said electrode being heated by the source of energy D. The local circuit containing the battery H or other source of electrical energy and the telephone F or other signal-indicating device is electrically connected with the electrodes C and I, and as shown is connected in series therewith. The antenna A may be associated with either electrode and in such case the other electrode may be connected to earth. It will be understood, however, that the particular mode of associating the oscillation responsive device with the antenna forms no part of my invention and that any suitable system of circuits may be employed with said oscillation responsive device.

The potential to be impressed upon the electrodes C and I by the battery H depends upon the nature of the gas intervening between said electrodes and upon the degree of exhaustion maintained within the receptacle B. I have found that from twenty-five to one hundred and ten volts is sufficient and by employing a higher degree of exhaustion a much smaller voltage may be used. The conductivity of the gas, which may be air, or a gas containing compounds of the halogens or halogen salts or which may be mercury vapor, is increased sufficiently to render said gas sensitive to the passage of electrical oscillations across the gap by the radiation of heat from the electrode C. The passage of electrical oscillations across said gap alters the conductivity of the gas in said gap, probably by changing the speed of the ions in said gas, and thereby current variations are produced in the circuit containing the battery H, the electrodes C and I, and the telephone F, causing said telephone to respond. When the telephone is in series with the battery H and the electrodes C and I, the passage of oscillations across the gap between said electrodes causes an increase of current through the telephone and if the telephone is connect-

ed in shunt with said electrodes, the passage of oscillations across the gap decreases the current through the telephone.

I do not wish to be limited to the particular embodiment of my invention which I have disclosed herein inasmuch as many modifications may be made therein by those skilled in the art without departing from the spirit of my invention.

This application is a division of my application, Serial No. 296,615, filed January 18, 1906.

I claim—

1. An oscillation-responsive device comprising a partially-exhausted receptacle, two separated electrodes sealed in said receptacle, means for heating one only of said electrodes, means whereby electrical oscillations may be impressed upon the gaseous medium intervening between said electrodes, and a local circuit including a source of electrical energy and a signal-indicating device electrically connected with said electrodes.

2. An oscillation-responsive device comprising a partially-exhausted receptacle, two separated electrodes sealed in said receptacle, means for heating one only of said electrodes, means whereby electrical oscillations may be impressed upon the gaseous medium intervening between said electrodes, and a local circuit including a source of electrical energy and a signal-indicating device connected in series with said electrodes.

3. An oscillation-responsive device comprising a partially-exhausted receptacle, two separated electrodes sealed in said receptacle, a source of electric current so associated with one only of said electrodes as to render the gaseous medium intervening between said electrodes sensitive to electrical oscillations, and a local circuit including a source of electrical energy and a signal-indicating device electrically connected with said electrodes.

4. An oscillation-responsive device comprising a partially-exhausted receptacle, separated electrodes sealed in said receptacle, means for heating one only of said electrodes, and a local circuit including a source of electrical energy and a signal-indicating device electrically connected with said electrodes.

5. An oscillation-responsive device comprising a receptacle, two separated electrodes inclosed within said receptacle, means for heating one only of said electrodes, means whereby electrical oscillations may be impressed upon the gaseous medium intervening between said electrodes, and a local circuit including a source of electrical energy and a signal-indicating device electrically connected with said electrodes.

6. An oscillation-responsive device comprising a receptacle, two separated electrodes inclosed within said receptacle, means for heating one only of said electrodes, means whereby electrical oscillations may be impressed upon the gaseous medium intervening between said electrodes, and a local circuit including a source of electrical energy and a signal-indicating device connected in series with said electrodes.

7. An oscillation-responsive device comprising a receptacle, two separated electrodes inclosed within said receptacle, a source of electric current so associated with one only of said electrodes as to render the gaseous medium intervening between said electrodes sensitive to electrical oscillations, and a local circuit including a source of electrical energy and a signal-indicating device electrically connected with said electrodes.

8. An oscillation-responsive device comprising a receptacle, two separated electrodes inclosed within said receptacle, means for heating one only of said electrodes, and a local circuit including a source of electrical energy and a signal-indicating device electrically connected with said electrodes.

In testimony whereof I have hereunto subscribed my name this 10th day of May, 1906.

OSCILLATION-RESPONSIVE DEVICE.

No. 867,876. Specification of Letters Patent. Patented Oct. 8, 1907.

Original application filed February 2, 1905, Serial No. 243,913. Divided and this application filed April 4, 1906. Serial No. 309,762.

To all whom it may concern:

Be it known that I, LEE DE FOREST, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented a new and useful Improvement in Oscillation-Responsive Devices, of which the following is a specification.

My invention relates to an improvement in the sensitive member used in systems of wireless telegraphy to detect electrical waves or oscillations and comprises the novel features hereinafter shown and described and particularly pointed out in the claims.

In the accompanying drawing I have shown, and in the description thereof will point out, one form of construction which may be employed in carrying out my invention.

The figure represents a receiving set for a wireless telegraphic system, having a sensitive member embodying the principles of my invention.

In the figure, A is an antenna or receiving conductor or wave intercepting means, E, the earth connection, P, the electrodes of the oscillation responsive device shown in the present case as included in series with the antenna and earth connection, G, a source of current, such as a dynamo, and T, the receiving or indicating instrument, which is herein shown as a telephone receiver, the same being shown only as typical of any form of indicating apparatus capable of being employed for such purpose.

I have discovered that if two bodies adapted for use as electrodes or conductive members be electrically separated, the separation between them may be neutralized sufficiently to enable them to act as a detector of electrical oscillations, if the intervening or surrounding gaseous medium be put into a condition of molecular and ionic activity, such, for instance, as would be caused by heating it in any manner, as by radiation, conduction or by the combustion of gases in the space which surrounds the electrodes. Such condition of molecular and ionic activity causes what would otherwise be a non-sensitive device to become sensitive to the reception of electrical influences. I am thus enabled to employ as such sensitive member devices which would otherwise be of no value and which comprise electrodes separated by a gaseous medium. This principle is embodied in the apparatus shown in the drawing in which the electrodes P are of sufficiently great resistance to be heated by a current from a dynamo G and by their radiation heat the gas between them. This gas may be air or the electrodes may be inclosed and surrounded by any suitable gas as shown, R being a receptacle inclosing said electrodes.

The influence of the oscillations upon the gaseous medium intervening between the electrodes P, which medium is maintained in a condition of molecular and ionic activity by the electrical means described, seems to vary the insulating quality of the gap so that while the influence of the oscillations lasts, the current of the local circuit is varied, thus affecting the indicating device T thereon to produce a signal. This may be due to ionization of the gas intervening between the electrodes which greatly increases the conductivity of said gas, said ionization being accomplished in the present instance by putting said gas in a condition of intense molecular activity.

This application is a division of my application Serial No. 243,913 filed February 2, 1905.

I claim:—

1. An oscillation responsive device comprising a receptacle inclosing a sensitive gaseous conducting medium, means for increasing the electrical conductivity of said gaseous medium, means for impressing electrical oscillations upon said medium, and means operatively connected therewith and responsive to alterations in the conductivity thereof.

2. An oscillation responsive device comprising a receptacle inclosing a sensitive gaseous conducting medium, electrical means for heating said gaseous medium, means for impressing electrical oscillations upon said medium and means operatively connected therewith and responsive to alterations in the conductivity thereof.

3. An oscillation responsive device, comprising a receptacle inclosing a gas, electrical means for rendering said gas sensitive to electrical oscillations, means for impressing electrical oscillations upon said gas and means operatively connected therewith and responsive to alterations in the conductivity thereof.

4. An oscillation responsive device comprising a receptacle inclosing a gas, electrical means for putting said gas in a condition of molecular and ionic activity, means for impressing electrical oscillations upon said gas and means operatively connected therewith and responsive to alterations in the conductivity thereof.

5. An oscillation responsive device comprising a receptacle inclosing a gaseous medium, means for rendering said gaseous medium sensitive to electrical oscillations and means for impressing electrical oscillations upon said gaseous medium.

6. An oscillation responsive device comprising a receptacle inclosing a gaseous medium, means for putting said medium in a condition of molecular and ionic activity whereby it will become the sensitive element of said oscillation responsive device, and means for impressing electrical oscillations upon said gaseous medium.

7. An oscillation responsive device comprising a receptacle inclosing a gaseous medium, electrical means for heating said medium and means for impressing electrical oscillations upon said gaseous medium.

8. An oscillation responsive device comprising a receptacle inclosing a gaseous medium, electrical means for rendering said medium sensitive to electrical oscillations and means for impressing electrical oscillations upon said gaseous medium.

9. An oscillation responsive device comprising an inclosed partially conducting gaseous medium, means for

ART OF DETECTING OSCILLATIONS.

No. 867,877. Specification of Letters Patent. Patented Oct. 8, 1907.

Original application filed February 2, 1905, Serial No. 243,913. Divided and this application filed June 12, 1907. Serial No. 378,503.

To all whom it may concern:

Be it known that I, LEE DE FOREST, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented a new and useful Improvement in the Art of Detecting Oscillations, of which the following is a specification.

My invention relates to an improvement in the art of receiving intelligible signals transmitted from distant stations by means of electric waves.

In the drawings which are hereto annexed and form a part of this specification, I have shown several forms of apparatus and circuit arrangements whereby my invention may be carried into effect, but it will be understood that my invention is not limited to the specific arrangements shown, as it may be variously embodied and applied.

Figure 1 is a diagrammatic view of a receiving circuit and apparatus embodying my invention. Fig. 2 is a similar view showing a modification. Fig. 3 is a similar view showing another modification. Fig. 4 is a similar view showing another modification. Fig. 5 is a similar view showing another modification. Fig. 6 is a similar view showing another modification. Fig.

...ionic activity and having dissociated and conducting ions.

I make no claim herein to the apparatus and circuit arrangements whereby my method may be carried into effect, inasmuch as such apparatus and circuit arrangements constitute the subject matter of my application Serial No. 283,913, filed Feb. 2, 1906, of which the present application is a division.

I claim:

1. As an improvement in the art of receiving electric signal waves, the method herein described which consists in establishing in a circuit a gaseous medium normally in a condition of molecular and ionic activity, impressing the electrical oscillations resulting from the waves to be received upon said gaseous medium and thereby altering the electrical condition of the circuit in which said gaseous medium forms a part and translating the resulting current variations into signal indications.

2. As an improvement in the art of receiving electric signal waves, the method herein described which consists in establishing in a circuit a gas having dissociated and conducting ions altering by the energy of the electric oscillations resulting from the waves to be received the conductive properties of said gas and translating the resulting current variations into signal indications.

UNITED STATES PATENT OFFICE.

LEE DE FOREST, OF NEW YORK, N. Y.

WIRELESS TELEGRAPHY.

No. 841,386. Specification of Letters Patent. Patented Jan. 15, 1907.

Application filed August 27, 1906. Serial No. 332,213.

To all whom it may concern.

Be it known that I, LEE DE FOREST, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented a new and useful Improvement in Wireless Telegraphy, of which the following is a specification.

My invention relates to wireless telegraphy and more particularly to an oscillation-detector which, in addition to performing the usual functions of such detectors, may be used as a tuning device and as a static valve, and which has a variety of other uses.

I have discovered that if the gaseous medium intervening between separated electrodes be put into a condition of molecular activity, as by heating the same or otherwise, said medium becomes highly sensitive to electrical oscillations, as more fully set forth in my application, Serial No. 243,913.

I have shown in my application, Serial No. 300,975, that the sensitiveness of an oscillation-detector comprising electrodes separated by such sensitive gaseous medium may be varied by the action of a magnetic field, so that the response of said detector *per se* is a function of a characteristic, such as the frequency, of the electrical oscillations operating upon the same. Thus, for certain frequencies a magnetic field of given strength will greatly decrease the sensitiveness of the detector and render it practically non-responsive, while for other frequencies the same magnetic field will greatly increase the sensitiveness of the detector. In short, said detector *per se* may be made selectively responsive without having recourse to tuned or resonant circuits, so that the use of such circuits may be dispensed with and the detector itself employed to perform the functions heretofore effected by said circuits.

The subject-matter of the present invention is an oscillation-detector which, like that above referred to, may be made selectively responsive to electrical oscillations having a given frequency or electrical rate of vibration but which does not require a proximate magnetic field for this purpose, and which also may be made selectively responsive to electrical oscillations having a given spark, or wave-train, frequency—that is to say, may be so adjusted that its response to electrical oscillations is a function of the number of groups or trains of waves per second, irrespective of the electrical frequency of such waves.

By virtue of the selective properties of my oscillation-detector as above set forth, I am enabled to employ said detector as a tuning device and also as a static valve or leak; and on account of its indestructibility I am enabled to employ the detector in those systems where large amounts of energy are created in the immediate proximity of said detector, such, for example, as the duplex systems described in my United States Letters Patent No. 772,879, dated October 18, 1904, and in the systems which permit "breaking" between two operators as set forth in my United States Letters Patent Nos. 827,523 and 827,524, dated July 31, 1906.

My invention may best be understood by having reference to the drawings which accompany and form a part of this specification and which diagrammatically illustrate four embodiments thereof which have successfully been employed; but I do not wish to limit myself to the details shown therein inasmuch as many other forms of construction and arrangement of circuits embodying the principles of my invention, as particularly pointed out in the appended claims, will readily occur to those skilled in the art.

In the drawings, Figure 1 represents a simple form of my oscillation-detector conductively connected with a receiving-antenna. Fig. 2 represents a detail of construction used in connection with the detectors shown in Figs. 1, 3 and 4. Fig. 3 represents a modification of the detector shown in Fig. 1 in which the detector is energized by an electric field developed by the oscillations to be detected. Fig. 4 represents a further modification in which the detector is energized by a magnetic field created by the oscillations to be detected.

In the figures, A is a receiving-antenna.

E is an earth connection.

M is a transformer, of which I, and I, are the primary and secondary windings.

B B' are batteries.

R R' are resistances.

L L' are inductances.

T is a telephone or other signal-indicating device.

D represents an evacuated vessel of glass or other suitable material having two separated electrodes F and F' between which intervenes the gaseous medium which, when sufficiently heated or otherwise made highly conducting, forms the sensitive element of

2800

...oscillation-detector. While various means may be employed for heating said gaseous medium, I find it convenient to employ electrical means and therefore I prefer to employ as the electrode F a filament of carbon or metal and to connect the same in series with a battery B and a rheostat R. I have discovered that a filament of metal especially one of platinum renders the oscillation-detector much more sensitive than one of carbon.

The electrode F may consist of a non-heated metallic body such as shown in the present instance as the wings or plates F' F'' secured to the metallic base 2, which may be supported by the upwardly extending portion 3 of the vessel D, although any suitable means may be used to support the electrodes F within said vessel.

While I have shown and described the electrode F as consisting of two wings or flat plates, it will be understood that said electrode may have any other form suitable for the purpose, although I have found that better results are obtained by using two flat plates or wings than by using a flattened cylinder or other such, a flattened cylinder gives better results than a cylinder of circular section. The reason for this is that the sensitiveness of the device, other things being equal, depends to a considerable upon the distance between the electrodes F F, and the greatest separation can be obtained by using flat plates for the electrode F. As will be obvious, the electrode F may consist of more flat plates.

The evacuated vessel D may be provided with a screw-socket 5, after the manner of ordinary incandescent lamps, and one end of the filament F may be conductively connected thereto, while the other end may be insulated therefrom and conductively connected to the contact-piece 4 in the base of the socket. In such case the terminals of the heating-battery B are connected respectively to the socket at 6 and to the contact-piece 4.

The terminals of the local circuit, which includes the battery B and signal-indicating device, such as the telephone T, are connected respectively to the electrodes F and F' at *a* and *b*. Means may be included in or associated with the local circuit for varying the potential developed by the local circuit B between the points *a* and *b*. For this purpose the number of cells which make up the battery B may be varied, or the adjustable resistance R, which, with the battery, constitutes a potentiometer, may be used.

The oscillation-detector, as above described, may be associated with the receiving system in a variety of ways now well known in the art by connecting the electrode F to one of the terminals of the source of oscillations and the electrode F' to the other terminal thereof. In the present instance the antenna A is connected to the electrode F' by a leading-in wire which is connected to the base 2 and which is sealed in the vessel D at *c*, and the earth-connector is connected to the electrode F through the socket 5 and the conductor 6*a*.

It is preferable that the positive pole of the battery B should be connected to the electrode F, and better results are obtained if the negative pole of the battery B be connected to that end of the filament F to which the positive pole of the battery B is connected, as shown in Figs. 1, 3, and 4, as that end of said filament which is connected to the screw-socket.

By regulating and adjusting the amount of heating-current flowing in the circuit of the battery B, the sensitiveness of my detector may be varied, so that the response of the detector *per se* will be a function of the frequency of the electrical oscillations operating upon the same, and said detector itself, as distinguished from the circuit in which it is included, will be selectively responsive to oscillations having a given electrical frequency. For regulating and adjusting the heating-current flowing through the filament F, I may employ the rheostat R or any other means suitable for the purpose.

For tuning the oscillation-detector to oscillations of given electrical frequency, the amplitude of the heating-current must be determined empirically, as by adjusting the rheostat R, because a number of factors such, for example, the separation of the electrodes F F, and the difference of potential developed by battery B across the points *a* *b* are involved.

By regulating and adjusting the potential impressed by the battery B across the electrodes F F', the sensitiveness of the detector may be varied so that the response of the detector *per se*, other things being equal, will be a function not only of the electrical frequency or wave length of the oscillations operating upon the detector, but also of the spark frequency which, *ceteris paribus*, is a measure of the total energy received, and the detector itself, as distinguished from a circuit tuned electrically to electrical or to spark frequency and from a mechanism tuned mechanically or acoustically to spark frequency, will be selectively responsive to oscillations having a given electrical frequency, and also to oscillations having a given spark frequency irrespective of their electrical frequency or wave length. Thus, with a given separation of the electrodes F F and a given amplitude of heating-current flowing through the filament F, I have been able by merely varying the potential of the battery B to attune the oscillation-detector to the oscillations developed in the receiving system by one of several transmitting systems and to receive the energy there-

3801

of to the exclusion of the energies of the oscillations developed therein by the other of said transmitting systems, even when the several sets of oscillations had the same electrical frequency and wave length, but differed in spark frequency or in average energy conveyed per unit of time. Here also the adjustment of the potential impressed by the battery B upon the electrodes F F' must be determined empirically.

By virtue of the selective properties of my detector, as above set forth, I am enabled to effect by the detector itself a method of double-tuning which affords the greatest security from waves the energy of which is not intended to affect the detector as well as from atmospheric or "static" electricity and other disturbing electrical forces.

As above mentioned, the sensitiveness of my oscillation detector, which in common with others of my invention employing a conducting gaseous medium as the sensitive element I call the "audion," is a function of the separation of the electrodes or of the length of the sensitive conducting gaseous medium; but I find that here again the frequency is a determining factor, so that by varying the separation of the electrodes I can make the response of the audion a function of the frequency. In other words, by suitably varying the length of the interelectrode medium, other adjustments, such as those of the batteries B B', remaining unchanged, I am enabled to make the audion *per se* selectively responsive to oscillations of a given frequency independently of the usual tuned or resonant circuit heretofore employed in wireless telegraphy as a current or oscillation selector.

A convenient means of varying the distance between the electrodes F F' is to hinge the wings which constitute the electrode F' to the base 2 as by the hinges 1 1. By approaching the magnets 6 6 to the inverted tube, as shown in Fig. 2, the wings, which may be made wholly or partly of iron, will open outwardly away from the filament and thereby increase the path of the conducting ions in the interelectrode medium.

When the audion is to be attuned to oscillations of a given frequency by varying the separation of the electrodes, the adjustment produced by the magnets 6 6 must be empirically determined, just as the adjustments of the batteries B B, above referred to are purely empirical.

It will be understood that each of the three methods above set forth for varying the response of the audion in accordance with the electrical frequency and the spark frequency of the oscillations to be detected may be separately employed and also that any two or all three of said methods may be used conjointly. For example, by appropriately varying the separation of the electrodes F F' and the amplitude of the heating-current from the battery B', the audion may be made selectively responsive to waves of a given electrical frequency, and then by the regulation and adjustment of the potential impressed upon the audion by the battery B, the audion may be made to select a particular one of a number of sets of waves all having the said electrical frequency and wave length, but each set having a spark frequency different from that of any other set.

The oscillation-detectors shown in Figs. 3 and 4 are identical in construction with those above described in connection with Figs. 1 and 2, and differ therefrom merely in the manner in which they are associated with the source of oscillations to be detected.

In Fig. 3, 7 represents a metallic member brought into proximity with the vessel D and shown in the present instance as a cylinder surrounding said vessel. In this case one terminal of the oscillation source which in the present instance is shown as a circuit including the secondary of the transformer M, is conductively connected to the cylinder 7 at the point *d*, while the other terminal may be connected to either one of the electrodes F or F' and in the present instance is shown as connected to the electrode F through the socket 5 and conductor *b c*. In this case the oscillating electric field developed by the electrical oscillations in the secondary circuit, which includes the secondary winding I_2, operates to alter the conducting properties of the sensitive conducting gaseous medium in the vessel D and thereby to vary the current flowing in the local circuit which includes the telephone T, just as in the case of the system shown in Fig. 1 in which the terminals of the oscillation source are connected directly to the interelectrode medium.

The arrangement shown in Fig. 3 affords a fourth method of rendering the audion selectively responsive, for in addition to the three methods above set forth in connection with Figs. 1 and 2 I find that, other things being equal, the response of the audion to oscillations of a given frequency is a function of the area of the surface of the number 7 and of the separation thereof from the elements within the vessel D.

If the form shown in Fig. 3 be employed, the cylinder 7 may be moved with respect to the axis of the vessel D until, *cæteris paribus*, the response of the audion is a maximum for oscillations of a given frequency. It will be understood of course that the separation of the electrodes F, F', and the values of the resistances R, R', of the audion shown in Fig. 3 may all be varied in the manner above explained in connection with Figs. 1 and 2.

When the connections shown in Fig. 3 are used I find that the quality of the sound produced in the telephone T is quite different

from that produced therein when the connections shown in Fig. 1 are used, although the sounds may be, and under the same conditions are, of equal intensity. When the connections shown in Fig. 1 are employed, the sounds produced by the telephone are sharp and crackling, as is the case where various other forms of oscillation-detector are employed, but when the connections shown in Fig. 3 are used, the sounds produced by the telephone, under the same conditions as before, are muffled or drummy. This latter sound is distinctive and is not produced by the use of any other form of oscillation-detector so far as I am aware. The advantage of obtaining the latter sound in the telephone is that it may readily be distinguished from the sounds produced therein by atmospheric electricity, whereas the sharp crackling sounds produced in the telephone by the signal-waves when other types of oscillation-detector are used very nearly imitate the sounds produced therein by static disturbances or atmospheric electricity.

In the arrangement shown in Fig. 4 the audion is energized by the oscillating magnetic field developed by the passage of the oscillations to be detected through the coil L, which surrounds the sensitive conducting gaseous medium and which in the present instance is wound around the outside of the tube. This coil preferably is made adjustable, as by the contacts *f* and *g*, and the antenna A may include an inductance L' having an adjusting-contact *e*. It will be understood that the adjustments of the separation of the electrodes F, F', of the amplitude of the heating-current and of the value of the potential impressed between the points *a* and *b*, as set forth above in connection with Fig. 1, may also be employed to render the audion shown in Fig. 4 selectively responsive. I have ascertained also that the variation of the magnetic field created by the passage of oscillations through the coil L varies the response of the audion, other things being the same, and furthermore that this variation also is a function of frequency. In other words, having adjusted the audion to be most responsive to oscillations of given frequency in the manner above described in connection with Fig. 1, there may be found empirically a certain position for the contacts *f* or *g*, at which for oscillations of a said frequency the response of the detector is a maximum.

The syntonizing-inductance L', or other electrical tuning device, may be employed in connection with any of the several embodiments of my present invention so as to combine the selectivity of the antenna or tuned receiving-circuit with the selective properties of the oscillation-detector itself, and in such cases I have found the selectivity of a receiving system so constructed to be very high indeed.

It will be understood that in all cases, if desired, the vessel D may include the vapor of a halogen salt or other substance the vapor of which is conducting or a gas whose conductivity is greater than that of air under an attenuated pressure.

I claim

1. An electrical-oscillation-selecting device comprising a vessel, a filament sealed in said vessel, a source of electric current connected in series with said filament, means for varying the amplitude of said current, whereby said device is rendered selective of electrical oscillations having a given electrical frequency, a member of conducting material inclosed within said vessel and a circuit connecting said member with said filament.

2. An electrical-oscillation-selecting device comprising a vessel, a filament sealed in said vessel, a source of electric current connected in series with said filament, a member of conducting material inclosed within said vessel, a circuit connecting said member with said filament, a source of electromotive force associated with said circuit and means for varying said electromotive force, whereby said device is rendered selective of electrical oscillations having a given spark frequency.

3. An electrical-oscillation-selecting device comprising a vessel, a filament sealed in said vessel, a source of electric current connected in series with said filament, means for varying the amplitude of said current, whereby said device is rendered selective of electrical oscillations having a given electrical frequency, a member of conducting material inclosed within said vessel, a circuit connecting said member and said filament, a source of electromotive force associated with said circuit and means for varying said electromotive force, whereby said device is rendered selective of electrical oscillations having a given spark frequency.

4. An electrical-oscillation-selecting device comprising a vessel inclosing a gaseous medium maintained in a condition of molecular activity; two electrodes inclosed within said vessel, and means for varying the separation of said electrodes.

5. An electrical-oscillation-selecting device comprising a vessel inclosing a gaseous medium maintained in a condition of molecular activity, two electrodes inclosed within said vessel, and means outside said vessel for varying the separation of said electrodes.

6. An electrical-oscillation-selecting device comprising a vessel, a filament sealed in said vessel, a source of electric current connected in series with said filament, a member of conducting material inclosed within said vessel, a circuit connecting said filament and said member and means for varying the separation of said filament and said member.

7. An electrical-oscillation-selecting device comprising a vessel, a filament sealed in

2803

said vessel, a source of electric current connected in series with said filament, and means for varying the amplitude of said current, whereby said device is rendered selective of electrical oscillations having a given electrical frequency.

8. An electrical-oscillation-selecting device comprising a vessel, a filament sealed in said vessel, a source of electric current connected in series with said filament, a member of conducting material inclosed within said vessel, a circuit connecting said filament with said member, a source of electromotive force associated with said circuit, means for varying said electromotive force and means for varying the separation of said filament and said member.

9. An electrical-oscillation-selecting device comprising a vessel, a filament sealed in said vessel, a source of electric current connected in series with said filament, means for varying the amplitude of said current, whereby said device is rendered selective of electrical oscillations having a given electrical frequency, a conductor inclosed within said vessel, a circuit connecting said conductor and filament, a source of electromotive force associated with said circuit and means for varying said electromotive force, whereby said device is rendered selective of electrical oscillations having a given spark frequency.

10. An oscillation-detector and means whereby said detector *per se* is rendered selective of electrical oscillations having a given spark frequency.

11. An oscillation-detector, means whereby said detector *per se* is rendered selective of electrical oscillations having a given electrical frequency and means whereby said detector *per se* is rendered selective to electrical oscillations having a given spark frequency.

12. An electrical-oscillation-selecting device comprising a vessel containing a sensitive conducting gaseous medium, two electrodes within said vessel, a local circuit connecting said electrodes, a receiving-circuit having one terminal connected with one of said electrodes, a conducting member outside said vessel and movable with respect thereto, and an electrical connection from the other terminal of said receiving-circuit to said conducting member.

13. An electrical-oscillation-selecting device comprising a vessel inclosing a gaseous medium maintained in a condition of molecular activity, two electrodes inclosed within said vessel, means for impressing an electrical potential upon said electrodes, and means for varying said potential.

14. An electrical-oscillation-selecting device comprising a vessel inclosing a gaseous medium, an electrode within said vessel, means for heating said electrode, means for regulating the temperature thereof, a second electrode inclosed within said vessel and a circuit connecting said electrodes.

15. An electrical-oscillation-selecting device comprising a vessel inclosing a gaseous medium, an electrode within said vessel, means for heating said electrode, means for regulating the temperature thereof, a second electrode inclosed within said vessel, means for impressing an electrical potential upon said electrodes and means for varying said potential.

16. An electrical-oscillation-selecting device comprising a vessel inclosing a gaseous medium maintained in a condition of molecular activity, two electrodes inclosed within said vessel, a local circuit connecting said electrodes and means for varying the separation of said electrodes.

17. An electrical-oscillation-selecting device comprising a vessel inclosing a gaseous medium, an electrode within said vessel, means for heating said electrode, means for varying the temperature thereof, a second electrode inclosed within said vessel and means for varying the separation of said electrodes.

18. An electrical-oscillation-selecting device comprising a vessel inclosing a gaseous medium, an electrode within said vessel, means for heating said electrode, means for varying the temperature thereof, a second electrode inclosed within said vessel, a circuit connecting said electrodes, an adjustable source of electromotive force associated with said electrodes, and means for varying the separation of said electrodes.

19. An electrical-oscillation detector comprising a vessel inclosing a gaseous medium, means for maintaining said gaseous medium in a condition of molecular activity, a member in proximity to said vessel, and an oscillation-circuit electrically connected to said member and to said gaseous medium.

20. An electrical-oscillation-selecting device comprising a vessel inclosing a gaseous medium, means for heating said medium, and means for varying the temperature thereof, whereby said device is rendered selective of electrical oscillations having a given electrical frequency.

21. An oscillation-detector comprising two conductively-connected flat plates of conducting material inclosed within an evacuated vessel, an electrode sealed within said vessel and located between said plates, and means for heating said electrode.

22. An oscillation-detector comprising two conductively-connected flat plates of conducting material inclosed within an evacuated vessel, a metallic filament sealed within said vessel and located between said plates, and means for heating said filament.

23. An oscillation-detector comprising two conductively-connected flat plates of con-

ducting material inclosed within an evacuated vessel, a filament of tantalum sealed within said vessel and located between said plates, and means for heating said filament.

24. An oscillation-detector comprising two flat plates of conducting material inclosed within an evacuated vessel, an electrode sealed within said vessel and located between said plates, and means for heating said electrode.

25. An oscillation-detector comprising two flat plates of conducting material inclosed within an evacuated vessel, a filament sealed within said vessel and located between said plates, and means for heating said filament.

In testimony whereof I have hereunto subscribed my name this 24th day of August, 1906.

UNITED STATES PATENT OFFICE.

LEE DE FOREST, OF NEW YORK, N. Y., ASSIGNOR, BY MESNE ASSIGNMENTS, TO DE FOREST RADIO TELEPHONE CO., A CORPORATION OF NEW YORK.

OSCILLATION-RESPONSIVE DEVICE.

979,275. Specification of Letters Patent. Patented Dec. 20, 1910.

Application filed February 2, 1905. Serial No. 243,913.

To all whom it may concern:

Be it known that I, LEE DE FOREST, a citizen of the United States of America, and a resident of the borough of Manhattan, city, county, and State of New York, have invented certain new and useful Improvements in Oscillation-Responsive Devices, the principles of which are disclosed in the following specification and accompanying drawings, which explain the form of the invention which I now consider to be the best of the various forms in which the principles of the invention may be embodied.

My invention relates to an improvement in the sensitive member used in systems of wireless telegraphy to detect the electrical waves or oscillations and comprises the novel devices hereinafter shown and described and particularly pointed out in the claims.

In the accompanying drawings I have shown, and in the description thereof will point out, certain forms of construction which may be employed in carrying out my invention and in connection therewith I will point out the principle of my invention.

Although by no means all the known or possible embodiments of my invention are herein illustrated or described, sufficient are given to make clear the principle of my invention.

Figures 1 to 6 inclusive each represents a receiving set for a wireless telegraph system, each having a sensitive member differing in appearance but all embodying the principle of my invention.

I have discovered that if two bodies adapted for use as electrodes or conductive members be electrically separated partially or fully, after the manner common in ataloguing devices, the separation between them may be neutralized sufficiently to enable them to act as a detector of electrical oscillations, if the intervening or surrounding gaseous medium be put into a condition of molecular activity, such for instance as would be caused by heating it in any manner, as by radiation, conduction, or by the combustion of gases in the space which surrounds the poles. Such condition or molecular activity causes what would otherwise be a non-sensitive device to become sensitive to the reception of electrical influences. I am thus enabled to employ as such sensitive member, devices which would otherwise be of no value, or to make those devices now used more sensitive to the electrical waves. This principle is embodied in the apparatus illustrated in the various figures shown.

In each of these figures, A represents the antenna or receiving conductor, or wave intercepting means; E, the earth connection; F, F', F'', F''', F'''', and F''''', the electrodes used in their various forms; B the local battery; and T, the receiving or indicating instrument, which is herein shown as a telephone receiver, the same being shown only as typical of any form of indicating apparatus capable of being employed for such purposes.

In Fig. 1 the two electrodes F, F, are slightly separated and are within the flame of an ordinary Bunsen burner D. Under these conditions the electrodes may be adjusted so that there is normally no indication of a passing current given by the receiving instrument, such as the telephone T. The electrical separation of the electrodes is however insufficient to prevent electrical oscillations from jumping the gap. The influence of these oscillations upon the heated gas seems to break down or lower the insulating quality of the gap, so that, while the influence of the oscillations lasts, the current of the local circuit may pass between the electrodes, thus affecting the indicating instrument therein to produce a signal. This may be due to ionization of the gases surrounding the electrodes which greatly increases their conductivity, said ionization being more or less accomplished or greatly facilitated by their previous heating which has already put them into a condition of intense molecular activity.

In Fig. 2 the electrodes F', F', are of sufficiently great resistance to be heated by a current from a dynamo G, and by their radiation heat the gas between them. This gas may be air or the electrodes may be inclosed and surrounded by any suitable gas as shown, for example, in Fig. 6 in which said electrodes are inclosed in the receptacle H. The heating of the gas may also be by radiation from the electrodes F', F'.

In Fig. 3, the electrodes assume the form of two parallel plates F'', F'' which are heated by a Bunsen burner. Although I have shown a Bunsen burner for this purpose, this particular heating device is not essential, as any means of heating may be employed.

In Fig. 4 the burner itself is made one

of the electrodes, the other of which is shown at F^3.

In Fig. 5 the local circuit is provided with electrodes F^4, F^4, and the oscillation-receiving circuit with separate electrodes F^5, F^5, both being heated by the flame of the Bunsen burner. The effect in this case is the same as before stated, that is the passage of the oscillations enables the current of the local circuit to jump the gap between the electrodes F^4, F^4 and thus to operate the receiving instrument. The oscillations apparently ionize the gas and thus temporarily reduce its insulating power or in other words increase its conductivity and enable the current of the local circuit to overcome the resistance between its poles. The action described may be effected by controlling the composition of the gases between and surrounding the electrodes or poles of the sensitive member. As an instance of this the addition of sodium or salts of the halogen class in the flame increases the ionization and conductivity of the gases and increases the sensitiveness of the device. Such control of the gases I consider to be within the scope of my invention.

While I have shown and described various means for securing this result I am aware that not all the possible means have been mentioned. Sufficient have however been described to indicate of what my invention consists. Any means for producing a heated gas with properly dissociated and conducting ions may be used.

I claim:

1. In a wireless telegraph system, the combination with separated electrodes connected to a wave intercepting means and to a local circuit, said electrodes being separated by a dielectric; of means coöperating with the received electrical oscillations for causing abnormal molecular activity in the intervening dielectric.

2. In a wireless telegraph system, the combination with separated electrodes connected to wave intercepting means and to a local circuit, said electrodes being separated by a dielectric; of means other than the received electrical oscillations, for heating the intervening dielectric.

3. In a wireless telegraph system, the combination with separated electrodes connected to a wave intercepting means and to a local circuit, said electrodes being separated by a dielectric; of a flame in the intervening dielectric.

4. In a wireless telegraph system, the combination with separated electrodes connected to a wave intercepting means and to a local circuit, said electrodes being separated by a dielectric; of means other than the received electric oscillations for changing the insulating quality of the intervening dielectric for the current of the local circuit.

5. In a wireless telegraph system, the combination with separated electrodes connected to a wave intercepting means and to a local circuit, said electrodes being separated by a dielectric; of means other than the received electrical oscillations, for changing the conductivity for the current of the local circuit, of the intervening dielectric.

6. In a wireless telegraph system, the combination with separated electrodes connected to a wave intercepting means and to a local circuit, said electrodes being separated by a dielectric; of a flame in the intervening dielectric, and a substance in the flame for increasing the conductivity of the gases.

7. In a wireless telegraph system, the combination with separated electrodes connected to a wave intercepting means and to a local circuit, said electrodes being separated by a dielectric; of means other than the received electrical oscillations, for maintaining a heated gas in the dielectric.

8. A sensitive detector for electrical oscillations, which comprises two electrodes and means for maintaining a heated gas therebetween.

9. A sensitive detector for electrical oscillations, which comprises two electrodes separated by a flame.

10. The combination with a detector of electrical oscillations, having separated electrodes, of means for maintaining between said electrodes, media in abnormal molecular activity.

11. The combination with a detector of electrical oscillations, having separated electrodes, of means for heating the intervening medium, and a substance in such heated medium which increases the conductivity thereof.

12. In a system of wireless or space telegraphy, the combination with intercepting means at a receiving station for intercepting electric waves transmitted through space from a transmitting station, of a detector in coöperative relationship with said wave intercepting means, for detecting the feeble oscillations caused by the intercepted waves to traverse said wave intercepter; a local circuit in coöperative relationship with said detector; an indicating device and a source of electromotive force coöperatively associated with said local circuit; said detector comprising two electrodes separated by an intervening di-electric, whereby both the received oscillations traversing said wave intercepting means and said local source of electromotive force, are normally inoperative with respect to said detector and indicating device; and means for establishing a heated gas in the space of separation between the electrodes of said detector, to permit the received oscillations to traverse such space and to thereby cause the local circuit of the local source of electromotive force to

operate said indicating device when oscillations are caused in the wave intercepting means by transmitted waves.

15. In a system of wireless or space telegraphy, the combination with intercepting means at a receiving station for intercepting electric waves transmitted through space from a transmitting station, of a detector in cooperative relationship with said wave intercepting means, for detecting the feeble oscillations caused by the intercepted waves to traverse said wave intercepter; a local circuit in cooperative relationship with said detector; an indicating device and a source of electromotive force cooperatively associated with said local circuit; said detector comprising two electrodes separated by an intervening dielectric, whereby both the received oscillations traversing said wave intercepting means and said local source of electromotive force, are normally inoperative with respect to said detector and indicating device; a gas burner, and means for conveying a supply of gas thereto, said burner being arranged so that its flame will intervene in the space of separation between the electrodes of said detector, to permit the received oscillations to traverse such space and to thereby cause the local circuit of the local source of electromotive force to operate said indicating device when oscillations are caused in the wave intercepting means by transmitted waves.

16. In a system of wireless or space telegraphy, the combination at a receiving station with intercepting means at a receiving station for intercepting electric waves transmitted through space from a transmitting station, of a detector in cooperative relationship with said wave intercepting means, for detecting the feeble oscillations caused by the intercepted waves to traverse said wave detector; a local circuit in cooperative relationship with said detector; an indicating device and a source of electromotive force cooperatively associated with said local circuit; said detector comprising two electrodes separated by an intervening dielectric, whereby both the received oscillations traversing said wave intercepting means and said local source of electromotive force, are normally inoperative with respect to said detector and indicating device; a burner, and means for conveying a supply of combustible matter thereto, said burner being arranged so that its flame will intervene in the space of separation between the electrodes of said detector to permit the received oscillations to traverse such space and to thereby cause the local circuit of the local source of electromotive force to operate said indicating device when oscillations are caused in the wave intercepting means by transmitted waves.

17. In a system of wireless or space telegraphy, the combination with intercepting means at a receiving station for intercepting electric waves transmitted through space from a transmitting station, of a detector in cooperative relationship with said wave intercepting means, for detecting the feeble oscillations caused by the intercepted waves to traverse said wave intercepter; a local circuit in cooperative relationship with said detector; an indicating device and a source of electromotive force cooperatively associated with said local circuit; said detector comprising two electrodes separated by an intervening dielectric, whereby both the received oscillations traversing said wave intercepting means and said local source of electromotive force, are normally inoperative with respect to said detector and indicating device; and means for establishing a heated gas in the space of separation between the electrodes of said detector, to permit the received oscillations to traverse such space and to thereby cause the local circuit of the local source of electromotive force to operate said indicating device when oscillations are caused in the wave intercepting means by transmitted waves; and a substance in said space of separation, which cooperates with the heated gas to increase the conductivity thereof.

16. In a system of wireless or space telegraphy, the combination at a receiving station with a detector of feeble oscillations caused by transmitted electromagnetic waves; of a circuit for said detector, which includes a source of electromotive force and an indicating device; said detector comprising two electrodes separated by an intervening dielectric, whereby both the received oscillations and source of electromotive force are normally inoperative with respect to said detector and indicating device; and means for establishing a heated gas in the space of separation between the electrodes of the detector, to permit the received oscillations to traverse said space and to thereby cause the circuit of the source of electromotive force to operate said indicating device when oscillations are received.

17. The combination with a detector of electrical oscillations of space telegraphy, said detector having electrodes separated by a dielectric, of means for heating the intervening dielectric, and a substance in said intervening dielectric which cooperates with said heating means to increase the conductivity of said dielectric.

18. An oscillation responsive device comprising a gaseous medium, means for increasing the electrical conductivity of said gaseous medium, means for impressing electrical oscillations upon said medium, and means operatively connected to said medium and responsive to alterations in the conductivity thereof.

19. An oscillation responsive device com-

3228

prising a gas, means for putting said gas in a condition of molecular activity, means for impressing electrical oscillations upon said gas and means operatively connected therewith and responsive to alterations in the conductivity thereof.

20. An oscillation responsive device comprising a gaseous medium and means for heating said medium.

21. An oscillation responsive device comprising a gaseous medium and means for putting said medium in a condition of molecular activity.

22. An oscillation responsive device comprising a sensitive gaseous conducting medium containing a halogen salt.

23. An oscillation responsive device comprising a sensitive gaseous conducting medium containing a halogen salt and means for heating said medium.

24. An oscillation responsive device comprising a sensitive gaseous conducting medium containing a sodium salt.

25. An oscillation responsive device comprising a sensitive gaseous conducting medium containing a sodium salt and means for heating said medium.

26. An oscillation responsive device comprising a sensitive gaseous conducting medium containing a halogen salt and means for putting said medium in a condition of molecular activity.

27. An oscillation responsive device comprising a sensitive gaseous conducting medium containing a sodium salt and means for putting said medium in a condition of molecular activity.

28. An oscillation responsive device comprising a gaseous medium and means for rendering said gaseous medium sensitive to electrical oscillations.

29. An oscillation responsive device comprising a gaseous medium and means for increasing the conductivity of the said gaseous medium to such an extent as to render the same sensitive to electrical oscillations.

30. A self-restoring, constantly receptive oscillation responsive device comprising in its construction a sensitive conducting gaseous medium.

31. A sensitive receiving member for wireless telegraphy having two poles separated by heated gas.

32. A sensitive receiving member for wireless telegraphy having two poles and means for surrounding the same with a heated gas.

33. A sensitive receiving member for wireless telegraphy having two poles surrounded by a flame.

34. A sensitive receiving member for wireless telegraphy employing a heated gas as a part of its conductive system.

35. In a sensitive receiving member for wireless telegraphy, the combination with two separated poles, of means for producing a condition of intense molecular activity in the medium intervening between said poles.

36. The combination with a sensitive receiving member for wireless telegraphy, of two separated poles and means for surrounding said poles with a medium which is continuously in a condition of intense molecular activity.

37. The combination with a sensitive receiving member for wireless telegraphy, of means for heating the medium intervening between the poles of said sensitive member and for introducing in said medium a substance adapted to increase its conductivity.

38. A sensitive receiving member for wireless telegraphy employing a gas maintained in a condition of molecular activity as a part of its conductive system.

39. In a sensitive receiving member for wireless telegraphy, the combination with separated poles, of means maintaining a condition of molecular activity in the medium intervening between said poles.

40. A wave detector having an electro-radiant wave detecting circuit including electrodes separated by an unconfined gaseous medium.

41. A wave detector having an electro-radiant wave detecting circuit formed in part by a body of free gaseous particles.

PLAINTIFF'S EXHIBIT 335

General. When there is a transfer of power from one circuit to another circuit, it is said that the two circuits are coupled. This transfer of power can be accomplished by electromagnetic or electric induction, or by resistance coupling. The coupling between circuits whether it is resistance, electromagnetic (inductive), or electric (capacitive), is divided into two classes, i.e., the direct and the indirect coupling.

Direct coupling refers to circuits where the coupling element is common to both circuits, whether it is an inductance, a capacity or a resistance. See figures 144, 145 and 146.

Fig. 144.—Direct Coupling by Inductance

Fig. 145.—Direct Coupling by Capacity.

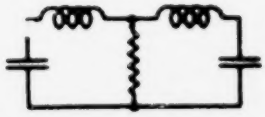

Fig. 146.—Direct Coupling by Resistance.

Indirect coupling is accomplished between circuits by magnetically coupling the inductances of each circuit or by capacitive coupling using condensers between the circuits, as shown in figures 147 and 148.

Fig. 147.

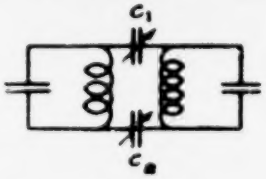

Fig. 148.

In figure 147, the transfer of power is accomplished magnetically and this power is proportioned to the distance between the two inductances, the closer the inductances the greater the transfer, while the farther apart the inductances are, the smaller the transfer. In other words, the closer the inductances the greater the electromagnetic induction while the farther apart the inductances are the smaller the electromagnetic induction.

32230

Figure 148 shows a method of indirectly coupling circuits by capacities. An increase in the value of the coupling capacities (C_1 and C_2) will increase the amount of power transferred from one circuit to another, while a decrease will reduce the power transfer.

In both methods of indirect coupling referred to, it is customary to refer to the condition of maximum power transfer as tight coupling and the condition of minimum power transfer as loose coupling. Coupling and coefficient of coupling are explained in detail in Chapter 7, Part 2.

If the coupling between two circuits is small, the two circuits will be resonant to one frequency but if the coupling is increased, both circuits, due principally to the effect of mutual inductance, will no longer be resonant to the original frequency, but will be resonant to two frequencies, one frequency being lower than the original frequency and the other being higher than the original frequency. With loose coupling it is possible to have each circuit resonant to one frequency, while if the coupling is tightened or increased in value, each circuit will be resonant to two frequencies.

The difference in frequencies referred to is dependent on the degree of coupling.

Figure 149 shows the resonance curve for a typical circuit when loosely coupled to another circuit, while figure 150 shows the same circuit under influence of a tight coupling.

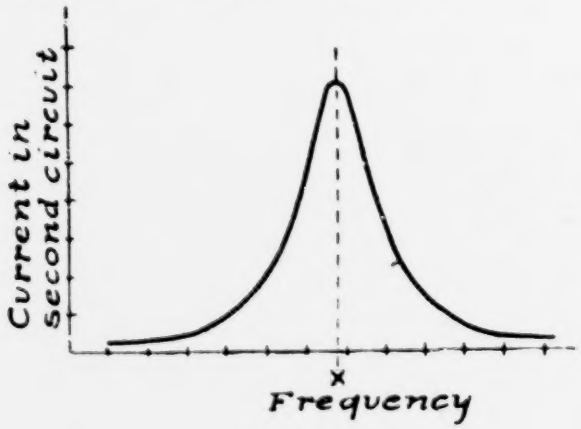

FIG. 149

In figure 149, X represents the resonant frequency of the circuit while X_1 and X_2 in figure 150 are the two frequencies to which the circuit is resonant when affected by tight coupling.

The question naturally arises why are the circuits resonant to two frequencies? The two circuits are resonant to two frequencies because of the fact that the mutual inductance of the circuits momentarily adds or subtracts from the inductance of each circuit.

The value of the inductance in each circuit varies momentarily and the circuits are resonant to two frequencies. The difference in

2812

the two frequencies depends on the value of mutual inductance or in other words on the coupling between the circuits. This may be represented

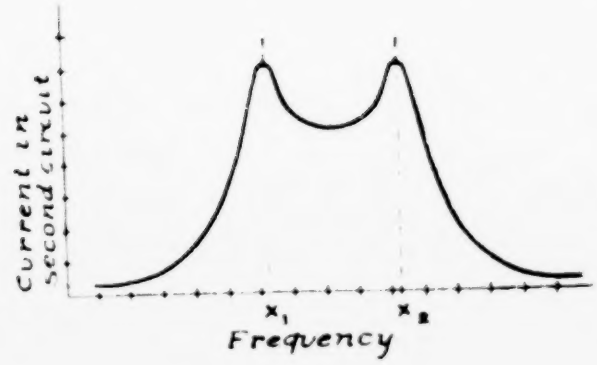

Fig. 150

by the following $L\,C$ equations which, in turn, have a definite relation to the frequency and wave length to which the circuits are resonant.

For loose coupling $$f = \frac{1}{2\pi\sqrt{L\,C}}$$

For tight coupling $$f_1 = \frac{1}{2\pi\sqrt{(L+M)\,C}}$$

and

$$f_2 = \frac{1}{2\pi\sqrt{(L-M)\,C}}$$

where

$$M = k\sqrt{L_1\,L_2}$$

L_1 being inductance of one circuit and L_2 the inductance of the other circuit.

When the coefficient of coupling is known, the two periods of resonance of the coupled circuits are found by the following:

$$\lambda_1 = \lambda\sqrt{1+k}$$

and

$$\lambda_2 = \lambda\sqrt{1-k}$$

where λ is the wave length to which the circuit is resonant to when acting singly, or very loosely coupled.

This phenomena of coupling and resonance of the circuits produces an effect in a spark transmitter where signals on two wave lengths are transmitted when tight or medium coupling is resorted to. In vacuum-tube or other undamped transmitters, although the two resonant fre-

At a Stated Term of the United States District Court for the Eastern District of New York, held in the Post Office Building in the Borough of Brooklyn, City of New York, on the 6th day of April, 1914.

Present: Hon. Van Vechten Veeder, United States Judge.

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA,
Complainant,

vs.

NATIONAL ELECTRIC SIGNALING COMPANY, Defendant

In Equity No. DE 31. On Marconi Patent No. 763,772

This cause having come on to be heard at final hearing upon pleadings and proofs taken and filed on behalf of both parties herein, and counsel for the respective parties having been heard, and due consideration having been had, it is, upon motion of Sheffield Bentley & Betts, solicitors for the complainant Ordered, Adjudged and Decreed as follows:

1. That Letters Patent of the United States in suit, issued to Guglielmo Marconi on June 28, 1904, No. 763,772, for "Apparatus for Wireless Telegraphy", are good and valid in law as to the 1st, 2nd, 3rd, 6th, 8th, 10th, 11th, 12th, 13th, 14th, 16th, 17th, 18th, 19th, and 20th claims thereof, which are as follows:

"1. At a station employed in a wireless telegraph system, a signaling instrument comprising an induction coil, the secondary circuit of which includes a condenser discharging [fol. 2815] through a means which automatically causes oscillations of the desired frequency; an open circuit electrically connected with the oscillation-producer aforesaid and a variable inductance included in the open circuit, substantially as and for the purpose described.

"2. At a station employed in a wireless-telegraph system, an oscillation-receiving conductor, a variable inductance connected with said conductor; a wave-responsive device electrically connected with said conductor and in circuit with a condenser, substantially as and for the purpose described.

"3. At a station employed in a wireless-telegraph system, a signaling instrument comprising an induction-coil, the secondary circuit of which includes a condenser discharging through a means which automatically causes oscillations of the desired frequency, and the primary circuit of which includes a generator; means for varying the primary circuit; an open circuit electrically connected with the oscillation-producer aforesaid, and a variable inductance included in the open circuit, substantially as and for the purpose described.

"6. At a transmitting station employed in a wireless-telegraph system, the combination of a transformer whose secondary is connected to an open circuit including a radiating conductor at one end and capacity at the other end, and whose primary is connected to a condenser-circuit discharging through a means which automatically causes oscillations of the desired frequency, and means for adjusting the oscillation period of each of the two circuits connected with the transformer to bring them into accord with each other, substantially as described.

"8. At a transmitting-station employed in a wireless-telegraph system, the combination of a transformer whose secondary is connected to an open circuit including a radiating-conductor at one end and capacity at the other end, a variable inductance being included in said circuit, and whose primary is connected to a condenser-circuit discharging through a means which automatically causes oscillations of the desired frequency, substantially as described.

"10. A system of wireless telegraphy, in which the transmitting station and the receiving station each contains an oscillation transformer, one circuit of which is an open circuit and the other a closed circuit, the two circuits at each station being in electrical resonance with each other and in electrical resonance with the circuit at the other station, substantially as described.

[fol. 2816] "11. In apparatus for communicating electrical signals, the combination, with an oscillation transformer, at a transmitting station, of an induction coil; an electric circuit containing the secondary of said coil, a condenser and the primary coil of the oscillation transformer; a producer of electric waves of high frequency electrically connected with the secondary of the induction-

coil; a signaling instrument in circuit with the primary of the induction-coil; the secondary coil of the oscillation-transformer electrically connected, at one end to capacity and at the other end to an inductance, and an aerial conductor connected to the inductance, substantially as and for the purpose described.

"12. In apparatus for communicating electrical signals, the combination, with an oscillation-transformer, at a transmitting-station, of an induction-coil; an electric circuit containing the secondary of the said coil, a condenser and the primary coil of the oscillation-transformer; a producer of electric waves of high frequency connected with the secondary of the induction coil; a signaling instrument in circuit with the primary of the induction-coil; the secondary coil of the oscillation-transformer electrically connected, at one end to capacity and, at the other end, to a variable inductance, and an aerial conductor connected to the variable inductance, substantially as and for the purpose described.

"13. At a receiving station employed in a wireless-telegraph system, the combination of an oscillation-transformer, an open circuit connected with one coil of said transformer, said circuit including an oscillation-receiving conductor at one end and capacity at the other end, a variable inductance being included in said circuit, a wave-responsive device electrically connected with the other windings of the oscillation-transformer, and a condenser in circuit with the wave-responsive device, substantially as described.

"14. At a receiving-station employed in a wireless-telegraph system, the combination of an oscillation-transformer, an open circuit connected with one coil of said transformer, said circuit including an oscillation-receiving conductor at one end and capacity at the other end, a wave-responsive device electrically connected with the other winding of the oscillation-transformer, and means for adjusting the two transformer-circuits in electrical resonance with each other, substantially as described.

"16. At a receiving-station, employed in a wireless-telegraph system, the combination of an oscillation-transformer, an open circuit connected with one coil of said transformer, said circuit including an oscillation-receiving conductor at [2817] one end and capacity at the other end, an adjust-

able condenser in a shunt connected with the open circuit and around said transformer coil, a wave responsive device electrically connected with the other coil of the oscillation-transformer, and means for adjusting the two transformer-circuits in electrical resonance with each other, substantially as described.

"17. At a receiving station employed in a wireless telegraph system, the combination of an oscillation-transformer, an open circuit connected with one coil of said transformer, said circuit including an oscillation-receiving conductor at one end and capacity at the other end, a wave responsive device electrically connected with the other winding of the oscillation transformer, and means included in each of said transformer circuits, for adjusting said circuits in electrical resonance with each other, substantially as described.

"18. At a receiving-station employed in a wireless telegraph system, the combination of an oscillation-transformer, an open circuit connected with one coil of said transformer, said circuit including an oscillation-receiving conductor at one end, and capacity at the other end, a variable inductance being included in said open circuit, a wave-responsive device electrically connected with the other winding of the oscillation-transformer, and a variable inductance included in circuit with the wave responsive device, substantially as described.

"19. In a system of wireless telegraphy, the combination at a receiving-station, of an oscillation-transformer; an open circuit comprising, in part, an aerial conductor connected with one end of the primary coil of the oscillation transformer; a connection from the other end of said coil to capacity; a variable inductance in said open circuit; and electrical connections from the secondary coil of the oscillation-transformer to a receiving instrument, battery, condenser, wave responsive device and a variable inductance, substantially as and for the purpose described.

"20. In a system of wireless telegraphy, a transmitting-station containing an oscillation transformer, the primary of which is connected to a condenser-circuit discharging through a spark-gap which automatically causes electric waves of the desired frequency, the secondary of said transformer connected to an open circuit including a radiating-conductor, and with a capacity and a coil for charging the

condenser aforesaid; a receiving-station containing an oscillation-transformer, the primary of which is connected with an oscillation-receiving conductor and with a capacity, a wave-responsive device connected with the secondary of said transformer, and a receiving instrument connected [fol. 2818] with the wave-responsive device, all in combination with means for bringing the four transformer-circuits, two at each station, into electrical resonance with each other, substantially as described."

2. That the complainant, Marconi Wireless Telegraph Company of America, is the sole and exclusive owner of said Letters Patent.

3. That the said Guglielmo Marconi was the first, true, original and sole inventor of the inventions described in said Letters Patent and claimed in said claims 1, 2, 3, 6, 8, 10, 11, 12, 13, 14, 16, 17, 18, 19 and 20 of said Letters Patent No. 763,772.

4. That the defendant, National Electric Signaling Company, has infringed upon said claims 1, 2, 3, 6, 8, 10, 11, 12, 13, 14, 16, 17, 18, 19 and 20 of said Letters Patent No. 763,772, by manufacturing, selling and using, or causing to be manufactured, sold or used, apparatus containing, embodying or employing the inventions of said claims 1, 2, 3, 6, 8, 10, 11, 12, 13, 14, 16, 17, 18, 19 and 20 of said Letters Patent.

5. That the complainant do recover of the defendant the profits, gains and advantages which the defendant has derived, received, earned or made, or which it shall derive, receive, earn or make by reason of the aforesaid or any infringement of the said 1st, 2nd, 3rd, 6th, 8th, 10th, 11th, 12th, 13th, 14th, 16th, 17th, 18th, 19th and 20th claims of said Letters Patent No. 763,772, and that the complainant do recover of the defendant any and all damages which the complainant has sustained or shall sustain by reason of the aforesaid or any infringement of the said 1st, 2nd, [fol. 2819] 3rd, 6th, 8th, 10th, 11th, 12th, 13th, 14th, 16th, 17th, 18th, 19th and 20th claims of said Letters Patent No. 763,772; and it is hereby referred to Richards M. Cahoone, Esq., as a Master of this Court, to take and state an account of said gains, profits and advantages and to assess such damages and to report to the Court thereon with all con-

venient speed; and the said defendant, its directors, officers, receivers, agents and employees, are directed and required to attend before said Master from time to time as required, and to produce before him such apparatus, books, documents, vouchers, and papers, and to submit to such oral examination or otherwise as the said Master may require in connection with said accounting and the assessing of said damages.

6. That a perpetual injunction issue out of and under the seal of this Court directed to the said defendant, National Electric Signaling Company, its associates, directors, officers, receivers, attorneys, solicitors, clerks, servants, agents, workmen and employees, enjoining and restraining them and each of them from directly or indirectly making or causing to be made, using or causing to be used, selling or causing to be sold, renting or leasing to others to be used, or disposing of in any manner whatsoever, threatening to make, sell, lease or use, advertising or offering for sale, lease or use, contributing to the manufacture, sale or use [fol. 2820] in any manner whatsoever, of apparatus, devices or appliances containing, embodying or employing the inventions of said claims 1, 2, 3, 6, 8, 10, 11, 12, 13, 14, 16, 17, 18, 19 and 20 of said Letters Patent No. 763,772 or any material or substantial part thereof, or from infringing upon or violating or from contributing to the infringement or violation of said claims, or either or any of them, or any material or substantial part thereof, in any way whatsoever.

7. That the complainant do recover of the said defendant, National Electric Signaling Company, the costs and disbursements of this suit to be taxed, and that the question of increase of damages and all further questions be reserved until the coming in of the Master's report.

(sgd.) Van Vechten Veeder, United States Judge.

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA,
Plaintiff,

vs.

NATIONAL ELECTRIC SIGNALING COMPANY and SAMUEL M. KINTNER and HALSEY M. BARRETT, Receivers of Said Company, Defendants.

In Equity. D E 31 On Marconi Patent No. 763,772

This cause having come on to be further heard at this term of the Court, and a certified copy of the order entered in the United States Circuit Court of Appeals for the Second Circuit on November 18th, 1914, dismissing the defendants' appeal from the interlocutory decree entered herein on April 6, 1914, having been filed herein on November 18th, 1914, and it appearing that a settlement has been made between the parties hereto, it is upon consideration, the consent of both parties and the motion of Sheffield, Bentley & Betts, solicitors for the plaintiff,

Ordered, Adjudged and Decreed that the said order of the Circuit Court of Appeals be and the same hereby is made the order of this Court, and that the said interlocutory decree entered herein on April 6, 1914, and all the provisions [fol. 2822] thereof, except that directing the recovery by the plaintiff from the defendant of damages, profits, gains and advantages for the infringement of the Marconi patent in suit No. 763,772, and ordering an accounting and assessment thereof, be and hereby are affirmed and made final herein, with costs and disbursements to the plaintiff.

Van Vechten Veeder, U. S. Judge.

We hereby approve the foregoing decree as to form and consent to the entry thereof.

Sheffield, Bentley & Betts, Plaintiff's Solicitors.
Herbert G. Ogden, Defendants' Solicitor.

At a Stated Term of the United States District Court for the Southern District of New York, Borough of Manhattan, City of New York, on the 9th day of October, 1916.

Present Hon. Julius M. Mayer, U. S. D. J.

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA,

Plaintiff,

DEFOREST RADIO TELEPHONE & TELEGRAPH COMPANY and LEE DEFOREST, Defendants

In Equity No. 12-31. On Fleming aPtent No. 803,684

INTERLOCUTORY DECREE

This cause having come on to be heard at final hearing, upon the pleadings and proofs taken and filed on behalf of both parties herein, and counsel for the respective parties having been heard, and due consideration having been had, it is, upon motion of Sheffield & Betts, solicitors for the plaintiff,

Ordered, Adjudged and Decreed as follows:

1. That the plaintiff, the Marconi Wireless Telegraph Company of America, is the sole and exclusive owner of United States Letters Patent No. 803,684, to John Ambrose Fleming, dated November 7, 1905.

2. That said Letters Patent No. 803,684 to John Ambrose [fol. 2824] Fleming are good and valid in law as to the first and thirty-seventh claims thereof, which are as follows:

"1. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for heating one of the conductors, and a circuit outside the vessel connecting the two conductors.

"37. At a receiving station in a system of wireless telegraphy employing electrical oscillations of high frequency, a detector comprising a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for heating one of the conductors, a circuit outside of the vessel connecting the two conductors, means for detecting a continuous current in the circuit, and means for impressing upon the circuit the received oscillations."

3. That the said John Ambrose Fleming was the first, true, original and sole inventor of the inventions described in said Letters Patent and claimed in said claims 1 and 37 of said Letters Patent No. 803,684.

4. That the defendant, DeForest Radio Telephone & Telegraph Company, has infringed upon said claims 1 and 37 of said Letters Patent No. 803,684, by manufacturing, selling and using, or causing to be manufactured, sold or used, apparatus containing, embodying or employing the inventions of said claims 1 and 37 of said Letters Patent.

5. That a perpetual injunction issue out of and under the seal of this Court, directed to the defendant DeForest Radio [fol. 2825] Telephone & Telegraph Company and its associates, officers, directors, attorneys, clerks, servants, agents, workmen and employees, enjoining and restraining them and each of them from directly or indirectly making or causing to be made, using or causing to be used, leasing or causing to be leased, selling or causing to be sold, advertising or offering for sale, use or lease, or causing to be advertised or offered for sale, use or lease, agreeing or contracting to sell or lease, or causing to be agreed or contracted for sale or lease, supplying or causing to be supplied, installing or causing to be installed, or threatening to make, use, lease, sell, supply or install, and threatening to offer or contract for sale, lease or supply, or disposing of in any manner, any devices, structures, appliances, instruments or wireless telegraph apparatus embodying or employing the said inventions and improvements or discoveries of the said 1st and 37th claims of said Letters Patent No. 803,684, or either of them, and from infringing upon or contributing to the infringement of said claims 1st and 37th of said Letters Patent, or either of them, in any way whatsoever.

6. That the defendant, DeForest Radio Telephone & Telegraph Company, is the sole and exclusive owner of the United States Letters Patent pleaded in the defendant's counterclaim, to Lee DeForest, as follows:

Nos. 824,637, dated June 26, 1906;
836,070, dated November 13, 1906;
837,901, dated December 4, 1906;
841,386, dated January 15, 1907;

[fol. 2826] Nos. 841,387, dated January 15, 1907;
867,876, dated October 8, 1907;
867,877, dated October 8, 1907;
867,878, dated October 8, 1907;
879,532, dated February 18, 1908, and
979,275, dated December 20, 1910.

7. That said Letters Patent No. 841,387 to Lee DeForest are good and valid in law as to the 4th and 6th claims thereof, which are as follows:

"4. In a device for amplifying electrical currents, an evacuated vessel, three electrodes sealed within said vessel, means for heating one of said electrodes, a local receiving-circuit including two of said electrodes, and means for passing the current to be amplified between one of the electrodes which is included in the receiving-circuit and the third electrode.

"6. In a device for amplifying electrical currents, an evacuated vessel, a heated electrode and two non-heated electrodes sealed within said vessel, the non-heated electrodes being unequally spaced with respect to said heated electrode, a local receiving-circuit including said heated electrode and that one of the non-heated electrodes which has the greater separation from the heated electrode, and means for passing the current to be amplified between the heated electrode and the other non-heated electrode."

8. That the said Lee DeForest was the first, true, original and sole inventor of the inventions described in said Letters Patent No. 841,387, and claimed in claims 4 and 6 thereof.

9. That said Letters Patent No. 879,532, dated February 18, 1908, are good and valid in law as to claims 2, 3, 6, 14, 18 and 21 thereof, which are as follows:

"2. An oscillation detector comprising an evacuated vessel, two electrodes inclosed within said vessel, means for heating one of said electrodes, and a conducting member inclosed within said vessel and interposed between said electrodes.

[fol. 2827] "3. An oscillation detector comprising an evacuated vessel, two electrodes inclosed within said vessel, means for heating one of said electrodes, and a grid shaped member of conducting material inclosed within said vessel and interposed between said electrodes.

"6. An oscillation detector comprising an evacuated vessel, two electrodes inclosed therein, means for heating one of said electrodes, a conducting member inclosed within said vessel and interposed between said electrodes, means for establishing a difference of electrical potential between said electrodes and means for preventing said conducting member from becoming electrically charged.

"14. An oscillation detector comprising an evacuated vessel, two electrodes, one of which is a filament, inclosed within said vessel, means for heating said filament, and a conducting member inclosed within said vessel and interposed between said electrodes.

"18. An oscillation detector comprising an evacuated vessel, two electrodes inclosed within said vessel, means for heating one of said electrodes, a grid of conducting material inclosed within said vessel and interposed between said electrodes, a local circuit including a source of electromotive force connecting said electrodes and a signal indicating device associated with said local circuit.

"21. An oscillation detector comprising an evacuated vessel, two electrodes inclosed therein, means for heating one of said electrodes, a conducting member inclosed within said vessel, a closed oscillation circuit, a circuit connecting one element of said oscillation circuit with one of said electrodes and said conducting member, a condenser in said circuit, a signal indicating device and a circuit connecting said device with the other of said electrodes and said conducting member."

10. That the said Lee DeForest was the first, true, original and sole inventor of the inventions described in said Letters Patent No. 879,532, and claimed in claims 2, 3, 6, 14, 18 and 21 thereof.

11. That a perpetual injunction issue out of and under the seal of this Court directed to the plaintiff, Marconi [fol. 2828] Wireless Telegraph Company of America, and its associates, officers, attorneys, clerks, servants, agents, workmen and employees, enjoining and restraining them, and each of them, from directly or indirectly making or causing to be made, using or causing to be used, leasing or causing to be leased, selling or causing to be sold, advertising or offering for sale, use or lease, or causing to be advertised or offered for sale, use or lease, agreeing or contract-

ing to sell or lease, or causing to be agreed or contracted for sale or lease, supplying or causing to be supplied, installing or causing to be installed, or threatening to make, use, lease, sell, supply or install, or threatening to offer or contract for sale, lease or supply, or disposing of in any manner, any devices, structures, appliances, instruments or wireless telegraph apparatus embodying or employing the said inventions and improvements or discoveries of said claims 4 and 6 of said Letters Patent No. 841,387, and claims 2, 3, 6, 14, 18 and 21 of said Letters Patent No. 879,532, or any of them, and from infringing upon or contributing to the infringement of said claims of said Letters Patent in any way whatsoever.

12. That the plaintiff, Marconi Wireless Telegraph Company of America, do recover of the defendant, DeForest Radio Telephone & Telegraph Company, the profits, gains and advantages which the defendant has derived, received, earned or made, or which it shall derive, receive, earn or make by reason of the aforesaid or any infringement of the [fol. 2829] 1st and 37th claims of said Fleming Patent No. 803,684; and that the plaintiff do recover of the defendant any and all damages the plaintiff has sustained or shall sustain by reason of the aforesaid infringement of the said 1st and 37th claims of said Fleming patent No. 803,684; and that the defendant, DeForest Radio Telephone & Telegraph Company, do recover of the plaintiff the profits, gains and advantages which the plaintiff has derived, received, earned or made, or shall derive, receive, earn or make by reason of the aforesaid or any infringement of the said 4th and 6th claims of United States Letters Patent No. 841,387 and claims 2, 3, 6, 14, 18 and 21 of United States Letters Patent No. 879,532; and that the defendant do recover of the plaintiff any and all damages which the defendant has suffered or shall sustain by reason of the aforesaid or any infringement of the 4th and 6th claims of said Letters Patent No. 841,387 and claims 2, 3, 6, 14, 18 and 21 of United States Letters Patent No. 879,532; and it is hereby referred to George C. Holt, Esq., as a Master of this Court, to take and state an account of said gains, profits, and damages, and to assess such damages and to report thereon to the Court with all convenient speed; and the said plaintiff and the said defendant and their directors, officers, agents and employees are directed and required to attend before said Master from

time to time as required and to produce before him such apparatus, books, documents and papers, and to submit to such oral examination or otherwise as the said Master may require in connection with said accounting and the assessing of said damages.

[fol. 2830] 13. That the plaintiff's bill of complaint as against the defendant Lee DeForest individually be dismissed.

14. That the defendant's counterclaim against the plaintiff upon Letters Patent No. 824,637, No. 836,070, No. 837,901, No. 841,386, No. 867,876, No. 867,877, No. 867,878, No. 979,275, and as to claim 5 of said Letters Patent No. 841,387, be dismissed.

15-a. That the plaintiff, Marconi Wireless Telegraph Company of America, do recover of the defendant, DeForest Radio Telephone & Telegraph Company, the costs and taxable disbursements incurred in defending defendants' counterclaim.

b. That the defendant, DeForest Radio Telephone & Telegraph Company, do recover of the plaintiff the costs and taxable disbursements, if any, in connection with the sustaining of claims 4 and 6 of United States Letters Patent No. 841,387 and claims 2, 3, 6, 14, 18 and 21 of United States Letters Patent No. 879,532.

c. That the defendant Lee DeForest do recover of the plaintiff the costs which he individually is entitled to recover as an individual defendant.

Julius M. Mayer, U. S. District Judge.

[Endorsed:] U. S. District Court, S. D. of N. Y. Filed Oct. 9, 1916.

[fol. 2831] PLAINTIFF'S EXHIBIT 348

UNITED STATES DISTRICT COURT, SOUTHERN DISTRICT OF NEW YORK

In Equity No. 12-31

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA,
Plaintiff,

vs.

DEFOREST RADIO TELEPHONE & TELEGRAPH COMPANY,
Defendant

And Now, To Wit, this 18th day of July, 1917, upon the return of the order of this Court dated January 22, 1917, and the motion of the plaintiff, requiring the defendant, De-Forest Radio Telephone & Telegraph Company, to show cause why the decree of this court, dated October 9, 1916, and the injunction issued in accordance therewith, restraining the defendant from infringing upon claims 1 and 37 of Fleming patent No. 803,684, do not cover and include certain devices heretofore manufactured and sold by the defendant; and upon consideration of the affidavit of Frank X. Waterman, verified January 18, 1917, filed in support of said order to show cause; and the affidavits of Lee DeForest and John Stone Stone, verified February 2, 1917, filed in opposition to said order to show cause; and the affidavits of Edwin H. Armstrong, Frank X. Waterman and Roy A. Weagant, verified April 18, 1917, filed in reply to said affidavits of DeForest and Stone and in further support of said order to show cause; and the affidavits of John Stone Stone and Robert F. Gowen, verified May 12, 1917, and of [fol. 2832] Charles V. Logwood and Walter A. Cohen, verified May 14, 1917, and of Lee DeForest, verified May 16, 1917, filed by the defendant in further opposition to the said order to show cause; and after hearing counsel for the respective parties, it is

Ordered, Adjudged and Decreed that, in addition to the devices or apparatus heretofore manufactured and sold by the defendant, and decreed to be an infringement of claims 1 and 37 of the Fleming patent in suit, that the devices or apparatus called by the defendant "amplifiers",

which have been manufactured and sold by the defendant separately, as well as the devices or apparatus which the defendant has manufactured and sold comprising "amplifiers" alone or in combination with other apparatus or instruments, are infringements of claims 1 and 37 of the Fleming patent in suit; and that any bulbs embodying claims 1 and 37 manufactured and sold by the defendant for use in such "amplifiers" or combination of "amplifiers" and other instruments or apparatus, are also an infringement of said claims 1 and 37 of the Fleming patent in suit, and that the injunction ordered to issue out of and under the seal of this Court by the interlocutory decree of October 9, 1916, shall cover and include each and all of such devices or pieces of apparatus, and that the defendant shall account to the plaintiff for all damages and profits which the plaintiff may be entitled to by reason of such infringing manufacture and sale, as provided for in the decree of October 9, 1916. [fol. 2833] And it is further Ordered, Adjudged and Decreed that the motion of the plaintiff with respect to the devices called by the defendant "oscillions," be and the same hereby is denied, without prejudice to the right of the plaintiff to renew said motion hereafter upon the filing of a new bill or a bill supplemental to the bill of complaint already filed. Future sales to U. S. Government are excepted from this order.

Julius Mayer, U. S. D. J.

Dated July 18, 1917.

At a stated term of the United States District Court for the Southern District of New York, held in the United States Court Rooms, in the Borough of Manhattan, City and State of New York, on the 9th day of July, 1919.

Present: Hon. Julius M. Mayer, U. S. D. J.

In Equity No. 12-31. On Fleming Patent No. 803,684

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA,
Plaintiff,

vs.

DEFOREST RADIO TELEPHONE AND TELEGRAPH COMPANY,
Defendant

This cause having come on to be further heard on the supplemental bill of complaint and answer and proofs taken

and filed on behalf of both parties herein and counsel for the respective parties having been heard and due consideration having been had, it is, upon motion of Sheffield & Betts, Solicitors for the Plaintiff,

Ordered, Adjudged and Decreed that in addition to the devices or apparatus heretofore manufactured and sold by the defendant and decreed to be an infringement of claim 1 of the Fleming patent No. 803,684, in suit, the devices or apparatus called by the defendant "oscillions" which have been manufactured and sold by the defendant separately, as well as the devices or apparatus which the defendant has manufactured and sold comprising "oscillions" alone or in combination with other apparatus or [fol. 2835] instruments are infringements of said claim 1 of the said Fleming patent in suit; and that any bulbs embodying said claim 1 manufactured and sold by the defendant for use in such "oscillions" or combination of "oscillions" and other instruments or apparatus, are also an infringement of said claim 1, of the said Fleming patent in suit; and that the injunction ordered to issue out of and under the seal of this Court by the Interlocutory Decree of October 9, 1916 and said Interlocutory Decree shall cover and include each and all of such devices or pieces of apparatus and that the defendant shall account to the plaintiff for all damages and profits to which the plaintiff may be entitled by reason of such infringing manufacture and sale as provided for in said Decree of October 9, 1916.

And It Is Further Ordered, Adjudged and Decreed that the plaintiff, Marconi Wireless Telegraph Company of America, do recover of the defendant, DeForest Radio Telephone and Telegraph Company, the costs and taxable disbursements in connection with said supplemental bill of complaint herein and the trial thereunder.

J. M. Mayer, U. S. District Judge.

It is hereby consented that the above order may be entered without further notice.

Sheffield & Betts, Plaintiff's Solicitors. Darby & Darby, Defendant's Solicitors.

[fol. 2836] PLAINTIFF'S EXHIBIT 363

House of Representatives

67th Congress, 1st Session

Report No. 173

Settlement of Damages for Infringements of Radio Patents

June 15, 1921.—Committed to the Committee of the Whole House on the state of the Union and ordered to be printed.

Mr. KAHN, from the Committee on Military Affairs, submitted the following Report. [To accompany H. R. 7111.]

The Committee on Military Affairs, to whom was referred the bill (H. R. 7111) authorizing the Secretary of War, the Attorney General, and the Secretary of the Navy jointly to make settlement of damages and compensation due by the United States for infringement of radio patents connected with the prosecution of the war, and for other purposes, having considered the same, report thereon with a recommendation that it do pass.

This bill was referred to the Committee on Military Affairs by the Speaker of the House in a communication signed, respectively, by the Secretary of War, the Attorney General, and the Secretary of the Navy, which reads as follows:

Departments of War, Justice, and Navy, *Washington, D. C., May 11, 1921.*

DEAR MR. GILLETT: We have the honor to invite attention to the situation that exists as a result of the use by the Government of patented inventions relating to radio communication and the development in that art.

Prior to the war with Germany the Government, principally the War and Navy Departments, found it necessary, because the validity of many patents relating to wireless telegraphy had not been judicially determined, to use wireless apparatus of various kinds without strict regard to the rights claimed by patentees, and during the war both departments used any and all apparatus, principles, and methods of known value without consideration of questions of infringement or proprietorship, giving where necessary

its warranty to contractors to protect them from litigation for infringement.

The development of this art has been very rapid and the patent situation with respect thereto is exceedingly complicated. There are many patents relating to the subject and a large number of claims for compensation for alleged use and infringement of patented inventions, among which there is much conflict, have been filed with the War and Navy Departments.

Realizing that the use by the Government had infringed the rights of many patentees while some of the claims possess little or no merit, and that a fair and reasonable determination of the whole matter would be difficult, long [fol. 2837] drawn out and expensive to the Government as well as to the claimants if an adjustment were not arrived at by a reasonable and business-like consideration of the interests of all parties concerned, a board designated "Interdepartmental Radio Board" was appointed by ourselves consisting of experts from the War Department, Department of Justice, and the Navy Department to consider all such claims, each with reference to its own merits and the merits of all the others. Such board has been considering the matter for nearly three years, giving all questions connected therewith careful, intelligent, and exhaustive consideration.

The claims presented to the board totaled many millions of dollars. Out of the 24 claims brought only 7 stated the amount of the compensation desired, and the total of those 7 was $14,800,000, the rest aggregating probably a much larger sum.

The board, giving due weight to matters of infringement, validity of patents, values of inventions, the circumstances of use by the Government, and the entire value of up-to-date wireless apparatus as the product of all inventions combined, has determined a sum of money that the Government should fairly and reasonably pay to the different patentees in proportion to the value of their respective inventions. Such sum will not exceed $2,500,000, which is only a small percentage of the aggregate sum claimed.

The owners of the various patents affected have been informed of the board's determination, and many or all of them have signified a willingness to accept the amounts allotted to them. The work of the board has been most pain-staking and careful, and its conclusions and determina-

tions reflect great credit upon its members. If settlement with the various patentees can be effected on the basis of the board's determination, a situation fraught with troublesome consequences would be disposed of to the great advantage of the Government and to the ultimate satisfaction of the claimants, and it is highly desirable, therefore, that provision be made for such settlements.

Therefore it is urgently recommended that the War, Justice, and Navy Departments be empowered to adjust and pay said claims on the basis of said board's determination.

Transmitted herewith is a draft of a provision that it is believed covers the matter adequately, and is suggested as an amendment to the act entitled "An act to provide relief in cases of contracts connected with the prosecution of the war, and for other purposes," approved February 2, 1919, commonly known as the Dent Act.

If at an early date payment could be tendered to all the claimants of the respective amounts found in their favor by said board, it is believed that all claimants having claims of substantial merit would accept settlement and release the Government, and it is earnestly requested that this matter be given favorable and prompt consideration by Congress.

Very sincerely, John W. Weeks, *Secretary of War.*
H. M. Daugherty, *Attorney General.* Edwin Denby, *Secretary of the Navy.*

Hon. Frederick H. Gillett, *Speaker of the House of Representatives.*

The testimony before the committee discloses the fact that during the World War it became necessary for the Government of the United States to seize radio telegraphic and telephonic appliances as a war emergency measure regardless of the rights of the patentees. The owners of these patents were given assurances that the Government would ultimately meet proper and just claims for the use of these patents.

The plan adopted and the work done during the past three years by the Departments of War, Justice, and Navy jointly reveals a most commendable and businesslike method of avoiding useless and expensive litigation and at the same time securing, on a very low basis to the Government, an adjustment of claims aggregating many millions of dollars.

The painstaking methods pursued in this instance by the

joint action of three Cabinet officers under the former administration and consummated and approved by the Secre-[fol. 2838] tary of War, the Attorney General, and Secretary of the Navy under the present administration furnish ample argument for the passage of this bill.

In the fall of 1918 the War and Navy Departments found themselves confronted with a large number of accrued and rapidly accumulating claims arising out of the necessary use by the Government of practically all the modern radio telegraphic and telephonic appliances without regard to the rights of patentees.

A large number of manufacturers were virtually ordered by the Government to furnish appliances which clearly infringed the patent rights of others, and at the same time gave assurance that the Government would assume and, at the close of the war, discharge such obligations as arose out of such infringements.

Foreseeing the intricate and expensive burden that would be imposed upon the Government if the various conflicting claims of various patentees on various instrumentalities were allowed to accumulate through a period of years, the Secretary of War, the Attorney General, and the Secretary of the Navy in the fall of 1918 appointed the "interdepartmental radio board" composed of the ablest experts in their respective departments to make a thorough investigation of all such claims then pending and likely to arise against the Government, and also to determine the relative rights of various patentees toward each other, with relation to patents on certain specific inventions, and furthermore to determine the comparative value of each patented instrument in cases where their simultaneous and joint use by the Government was found necessary. The creation of this board was also more formally verified by the precept of the three Cabinet officers on February 12, 1921. This board for more than two full years assiduously devoted itself to hearings and investigations and succeeded in reducing the claims aggregating approximately $30,000,000 to a settlement basis of $2,500,000, and beyond this all the principals to whom it finds the Government under legal obligation, have been induced to settle on this reduced basis if payment can be effected without delay.

The practical value to the Government of the plan adopted has been so pronounced that the British Government, after

studying it, has adopted it for settlement of claims of similar and other character.

During the progress of the investigation it developed that there are approximately 2,500 United States patents in this art, all of which were living during the period covered by the board. All of these have had to be considered in one way or another; if not directly as patents under which claims are made, then as to their bearing on patents under which claims were made. In addition, hundreds of foreign patents and hundreds of United States and foreign publications have been sought out and considered in relation to their effect on those patents presented in the claims.

The claimants did not know precisely just what the Government had used, and many of them brought claims under all patents, with the result that the board had to laboriously proceed through several hundred patents, pick out those under which it was evident there was no infringement; and then by hearings with claimants, long drawn out, eliminate the chaff.

The board finally came down to a real serious consideration of 149 patents. This consideration involved searches [fol. 2339] of the art, writing of long reports, receipt of briefs from claimants, hearings, more briefs, revised reports, and then an accounting on those patents considered good, which were 27 in number, with much discussion following as to the methods of accounting and the effect of decisions thereon.

Such a task has been stupendous, and has required a force of experts—expert to begin with, but which became more expert daily in its specific task as it gained knowledge from experience.

Consider the chaos that would have existed if such a task (the serious consideration of 149 patents of a difficult art) had been presented to a number of courts in different places and at different times; for a single patent could be the cause of half a dozen suits in order to reach the numerous contractors for the Government; and then, after the patents had been sustained, the long drawn out procedure of accounting in each case, each accounting duplicating in many respects accountings in other jurisdictions.

Under our judicial system, and with the extreme difficulty in presenting petent cases, it is probable that the task could not have been covered in the courts in 25 years in the same comprehensive but centralized method of the board.

The Secretary of War, the Attorney General, and the Secretary of the Navy urge these settlements without delay and request the necessary legislation.

[fol. 2840] PLAINTIFF'S EXHIBIT 364

UNITED STATES DISTRICT COURT, WESTERN DISTRICT OF WASHINGTON, NORTHERN DIVISION

No. 71. In Equity

MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA,
Plaintiff,

vs.

KILBOURNE & CLARK MANUFACTURING COMPANY, Defendant

On Lodge Patent No. 609,154 and Marconi Patent No. 763,772

FINAL JUDGMENT

At a Regular Term of the United States District Court for the Western District of Washington, Northern Division, held in the Federal Building, in the City of Seattle, on the 16 day of July, 1917.

Honorable Jeremiah Neterer, United States District Judge, Presiding

This cause came on to be further heard at this term and was argued by counsel;

And thereupon, upon consideration thereof, it was Ordered, Adjudged and Decreed as follows:

1. That letters patent of the United States issued to Oliver J. Lodge on the 16th day of August, 1898, No. 609,154, during the term thereof, were good and valid in law, as to claims 1, 2 and 5 thereof.

2. That the plaintiff, Marconi Wireless Telegraph Company of America, was the sole and exclusive owner of said Letters Patent No. 609,154 during the term thereof.

3. That the said Oliver J. Lodge was the first, true, original and sole inventor of the inventions described in said [fol. 2841] letters patent and claimed in said claims 1, 2 and 5.

4. That the defendant, Kilbourne & Clark Manufacturing Company, during the term of said Letters Patent, and before its expiration, infringed upon said claims 1, 2 and 5 of said Letters Patent, by manufacturing and selling apparatus containing, embodying or employing the inventions of said claims 1, 2 and 5 of said Letters Patent No. 609,154, or material or substantial parts thereof

5. That the defendant has paid the plaintiff the sum of Four Thousand Dollars ($4000.00) in full of all claims for damages, gains and profits by reason of the aforesaid infringement of said claims 1, 2 and 5 of said Lodge Patent, including all claims against defendant's customers therefor, but exclusive of claims against the United States of America for apparatus infringing the said Lodge Patent manufactured or sold by the defendant herein for or to the United States of America, as per stipulation of the parties on file herein.

6. That the said patent having expired pending suit, no injunction shall issue restraining the said infringement.

7. That said Letters Patent of the United States issued to Guglielmo Marconi on June 28, 1904, No. 763,772, for apparatus for wireless telegraphy, are good and valid in law as to claims 1, 2, 3, 6, 8, 10, 11, 12, 13, 14, 16, 17, 18, 19 and 20, when properly construed in connection with the apparatus described in the specification of said patent, as more fully appears in the opinion herein filed.

8. That the plaintiff, Marconi Wireless Telegraph Company of America, is the sole and exclusive owner of said [fol. 2842] Letters Patent No. 763,772.

9. That the said Guglielmo Marconi was the first, true, original and sole inventor of the inventions described in said Letters Patent and claimed in the said claims 1, 2, 3, 6, 8, 10, 11, 12, 13, 14, 16, 17, 18, 19 and 20 thereof.

10. The manufacture and sale by the defendant of *of* its wireless apparatus known as the "Thompson Transmitter", the "Simpson Transmitter", and its Standard Receiver, or

either of them, as set forth, shown and described in the proofs herein, does not infringe upon the inventions described in said Letters Patent No. 763,772, and claimed in said claims 1, 2, 3, 6, 8, 10, 11, 12, 13, 14, 16, 17, 18, 19 and 20 thereof, or any of them.

11. In view of the Act approved June 25, 1910, entitled "An Act to Provide Additional Protection for Owners of Patents of the United States and for Other Purposes", the Court has no jurisdiction to grant the prayer of the bill for an injunction and an accounting in respect to the wireless telegraph apparatus manufactured and sold by the defendant to the United States Government, a set of which was installed on the Steamship "Achilles", and the Court, therefore, makes no finding upon the question of whether said apparatus infringes the patent in issue.

12. That the prayer of the bill, so far as it seeks an injunction and an accounting in respect to defendant's said wireless telegraph apparatus installed on the Steamship "Achilles" as an infringement of each of the aforesaid claims of the said Lodge Patent No. 609,154 and Marconi [fols. 2843-2844] Patent No. 763,772, and so far as it relates to an injunction and an accounting in respect to the defendant's aforesaid "Thompson Transmitter", "Simpson Transmitter" and its Standard Receiver as infringements of each of the aforesaid claims of Marconi Patent No. 763,772, be and hereby is denied, and the bill of complaint, so far as it relates to such apparatus as infringements of said claims be and hereby is dismissed.

14. That no costs or disbursements heretofore incurred by either plaintiff or defendant in this proceeding be allowed or taxed in favor of either party hereto.

To paragraphs No. 10, 11, and 12 hereof, and each thereof, the plaintiff excepts, and said exceptions are hereby allowed.

Jeremiah Netterer, United States District Judge.

DESCRIPTION AND DIRECTIONS FOR THE USE OF U.S. NAVY

SHORT WAVE RECEIVER

TYPE SE 143

This instrument is designed primarily for the reception of spark signals; secondarily for the reception of long, sustained waves, using an audion control box as a detector. A four pole, double throw switch in the receiver permits of the use of either crystal detector or audion, both of which may be permanently connected to the receiver.

The range of the primary of this receiver is 250 to 3100 meters. The range of the tuned secondary is 250 to 3800 meters. The primary may be increased from its normal range of 3100 meters to over 7000 meters on any antenna by connecting as shown in Fig. 1.

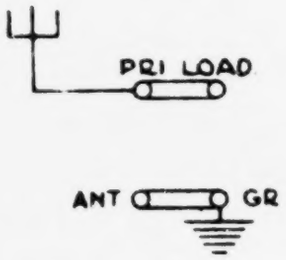

Fig. 1.

This places the primary variable condenser in parallel with the primary inductance. This combination is very efficient on waves longer than 3000 meters; on short waves, it is not as efficient as the series capacity.

The change over from shunt to series connection can be made quickly by using a double pole double throw switch as shown in Fig. 2.

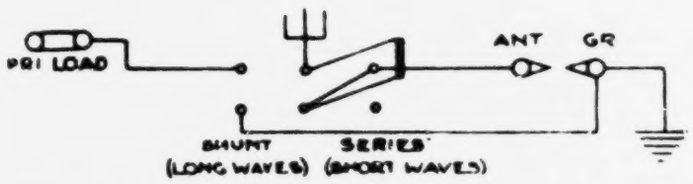

Fig. 2.

The receiver circuit, with detector switch on "AUDION", is shown schematically in Fig. 3.

DETAILED SPECIFICATIONS

ANTENNA CIRCUIT:

The antenna circuit of this receiver has a wave length range of 250 to 3100 meters when used with an antenna of 0.0008 mf. capacity. A greater range may be obtained by connecting the primary condenser in parallel with the primary inductance as previously described. The antenna circuit consists of a large, air dielectric, variable condenser, minimum capacity about 0.00008 mf. and maximum capacity 0.0045 mf.; a primary cylindrical loading coil, a primary coupling coil, inductance switches and coil cutouts.

The cylindrical loading coil consists of a micarta tube 5 inches outside diameter and 6.625 inches long, wound with a double bank winding of 212 turns of 3x16x38 Belden Litzendraht, and has an inductance of 3.8 millihenries.

The primary coupling coil is 5 inches in outside diameter, 2 inches long, wound with a double bank winding of 47 turns of 3x16x38 Belden Litzendraht, and has an inductance of 0.42 millihenries.

The primary loading coil is wound in two sections; an air gap of 5/16 inch separating the first 94 turns from the remaining 118. This sectionalizing scheme is adopted to cut down both the distributed capacity and the natural period of the coil.

The primary condenser is of the balanced plate type. The fixed and movable plate systems are in two sections arranged 180 degrees from each other to balance the movable plate system mechanically. A knob marked FINE ADJUSTMENT is mounted on the receiver panel to the left and below the handle of the variable condenser. This knob permits of fine adjustment of the primary condenser through gears connected to the movable plates. A small sector, of 7 degrees, is cut from each end of the movable plates of the condenser. A sector, of 10 degrees, is cut from each end of the fixed plates of the condenser. This increases the ratio of maximum to minimum wave length of each coil, by reducing the end plate capacity to a minimum. The movable plate system carries a German silver dial on which the antenna wave lengths may be marked either in pencil or in India ink. An external loading coil may be inserted into the antenna circuit by connecting to the binding posts marked PRI. LOAD. COIL after removing the short circuiting link.

SECONDARY CIRCUIT:

The secondary circuit has a wave length range of from 250 to 6800 meters. There is an overlap of at least 35 per cent. on each of the steps of secondary coil.

Fig. 92 represents circuits of a receiving set complying with present specifications. In all such sets closed circuits are calibrated and curves drawn or a scale furnished showing wave lengths for all settings from 200

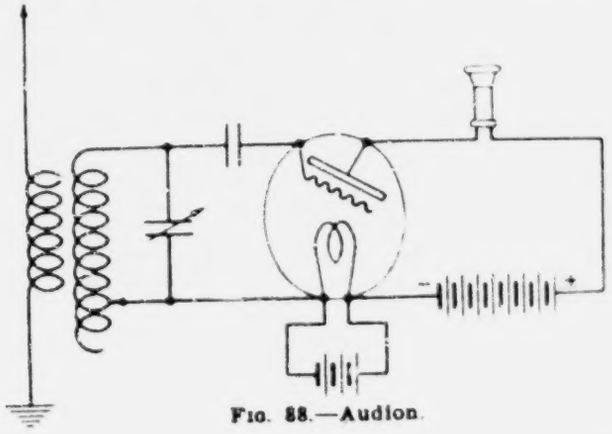

FIG. 88.—Audion.

to 4000 meters, and additional calibrated loading coils for very long waves are supplied.

With very loose coupling the wave length of received signals can thus be read directly.

200. Fig. 89 represents receiving circuits for continuous oscillations; it shows the receiving telephone connected across the terminals of a fixed condenser in series with the detector.

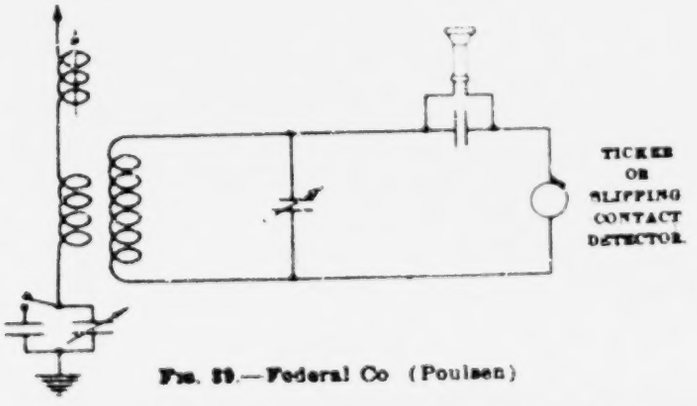

FIG. 89.—Federal Co (Poulsen)

In using undamped oscillations for wireless telegraphic purposes it must be remembered that the frequency of the oscillations themselves is too high to be heard in the telephone connected with the ordinary receiving circuit, and when the circuit at the sending station is closed all that would be heard is a slight click, so that there is no way of telling a

2863

3276

as possible. With properly adjusted carbons, the instrument should operate an hour without attention and then requires only the careful cleaning and facing up of the carbons.

202. In spark sets we want the sending aerial to be a good radiator, but not so good that it will give a whip crack discharge. We want its oscillations to be persistent enough to require for their best reception a receiving aerial tuned to the period of the sender, and as a present standard we have set for the sender a damping considerably less than .2, so that it makes fifteen complete oscillations before the oscillating current falls to 1 of its original value. We want the receiving aerial to radiate as little

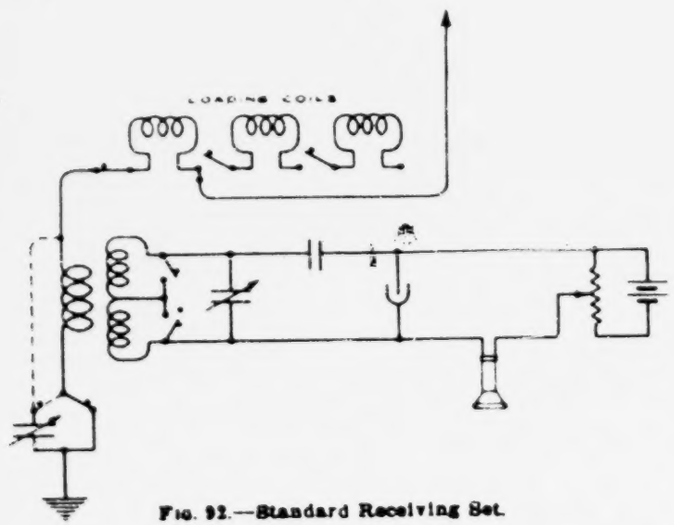

FIG. 92.—Standard Receiving Set.

as possible; but to so combine the energy of the fifteen waves that the highest maximum is produced in the aerial, and transferred to the closed receiving circuit.

If the sending aerial is coupled so as to send out waves of two lengths, there appears to be no question that the coupling of the receiving circuits should be such that, if they acted as senders, they would send out waves of these lengths, or so loosely coupled that their natural period is that of the arriving wave containing the most energy. If, in the case of very loosely coupled circuits or those supplied with quenched spark gaps, but one wave length is being radiated, receiving circuits should also be loosely coupled or should be coupled so that the transfer of energy from the open to the closed circuit and the damping of the latter (with the detector, however connected) is at such a rate that a maximum current in the closed circuit is reached at the instant the open circuit has come

RECEIVING.

249. In ordinary circumstances, while listening in, the set may be kept closely coupled, to broaden the tune; but the aerial circuit should be *stiff*, i. e., having a considerable amount of inductance (art. 231). The aerial circuit should be tuned with a variable condenser in series for short waves and in parallel (around inductance) for long waves (fig. 92).

When the calling station is well tuned in, loosen the coupling, if there is interference. This should be done gradually, *adjusting both the open (aerial) and closed circuits with each change of coupling*, until a point is reached where signals are readable through the disturbances. With fairly strong signals the coupling on a 1 P. 76 receiver should be not less than 16 on the coupling scale, and, at this point, for moderate wave lengths, the signal should not fall materially in intensity.

For further improvements in tuning, the closed circuit condenser should be made as large as possible and the closed circuit inductance correspondingly reduced.

The settings (for best coupling and of open and closed circuits) for all stations habitually communicated with should be recorded and posted for the use of the operator on watch.

The practice of loosening coupling while receiving should be *made obligatory* on all operators. It not only cuts out existing interference, but prepares for any interference which may arise during reception. Owing to the change of effective self-induction, in both circuits, both require readjustment (retuning) with each change of coupling.

Two aerials in the same immediate vicinity as on board the same ship have an influence on each other so that if both are used for receiving at the same time, the tuning of either will affect the other and this effect may be observed between aerials on different ships if they are very close together.

250. When two ships are close together, the one which is not doing the sending can generally assist in receiving faint signals. Regardless of opening of circuits, high power sending lessens the sensitiveness of the

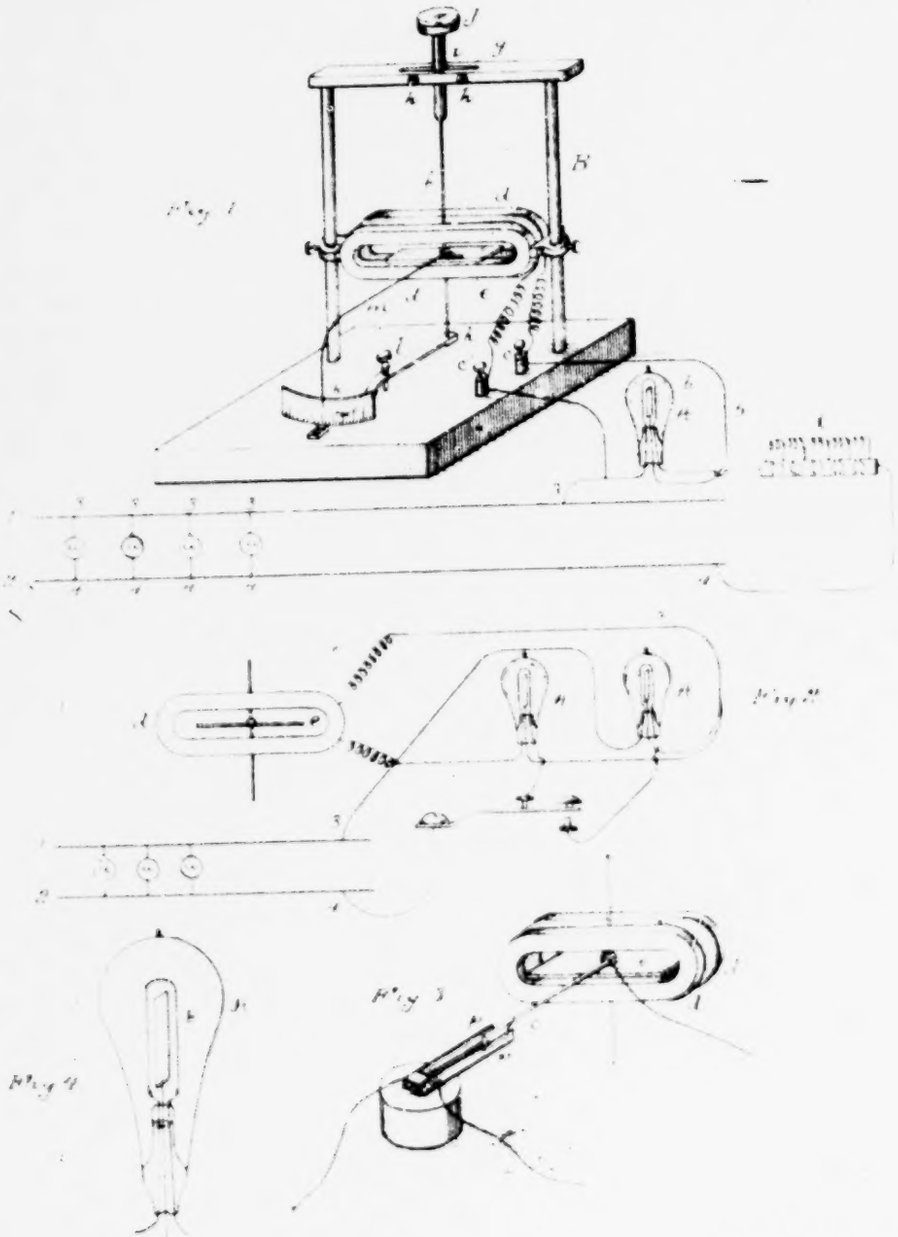
(No Model.)

T. A. EDISON.

ELECTRICAL INDICATOR.

No. 307,031. Patented Oct. 21, 1884.



ATTEST

2884-2885

32,937

UNITED STATES PATENT OFFICE.

THOMAS A. EDISON, OF MENLO PARK, NEW JERSEY.

ELECTRICAL INDICATOR.

SPECIFICATION forming part of Letters Patent No. 307,031, dated October 21, 1884.

Application filed November [illegible], 1884. (No model.)

To all whom it may concern:

Be it known that I, THOMAS A. EDISON, of Menlo Park, in the county of Middlesex and State of New Jersey, have invented a new and useful Improvement in Electrical Indicators, (Case No. 693,) of which the following is a specification.

The object of my invention is to produce an efficient apparatus for indicating variations of electro-motive force in an electric circuit, preferably for use in connection with systems of electrical distribution to show the changes in pressure in the various parts of the district. The apparatus is also capable of use in automatically regulating the electro motive force to correspond with such variations. I have discovered that if a conducting substance is interposed anywhere in the vacuous space within the globe of an incandescent electric lamp, and said conducting substance is connected outside of the lamp with one terminal, preferably the positive one, of the incandescent conductor, a portion of the current will, when the lamp is in operation, pass through the shunt-circuit thus formed, which shunt includes a portion of the vacuous space within the lamp. This current I have found to be proportional to the degree of incandescence of the conductor or candle-power of the lamp.

My invention consists in the utilization of this discovery for indicating or regulating variations in electro motive force, or for affecting electrical apparatus in any desired manner. By connecting a device for indicating current changes in the shunt-circuit, changes in the candle power of the lamp, and consequently in the electro motive force of the source of supply, are made apparent; or if, instead of an indicating device, the variations in electro motive force are made to affect circuit-controlling apparatus, automatic regulators or other electrical apparatus may be controlled thereby.

In applying my invention to a system of incandescent electric lighting I place a standard lamp having within its globe a piece of platinum, preferably a thin plate, though platinum wire may be used, placed preferably between the limbs of its carbon conductor, such platinum piece being in connection with the circuit whose electrical condition is to be observed, connecting said piece to a point similarly to those of the other lamps of the system, and making an additional connection from the positive terminal, preferably, of the lamp-circuit, to one terminal of a galvanometer or other indicator, and from the platinum piece through a wire sealed in the glass to the other terminal of the galvanometer or indicator. The galvanometer, if one is used, is provided with a torsional device for holding its needle at zero under a normal current, so that variations of a few volts from the normal deflect the needle to one direction or the other. If the electro motive force in the system, and consequently the candle-power of the lamps, increases, the indicating lamp varies with the rest, and the current from it to the galvanometer is increased, causing the deflection of the galvanometer needle; and conversely, a decrease in electro motive force in the system produces an opposite deflection. The galvanometer needle may be made to close circuit to electrically operated devices for accomplishing the automatic regulation of the generator supplying current to the system or for any other purpose.

My invention is illustrated in the annexed drawings.

Figure 1 is a diagram of the system and connections, with a view in perspective of the galvanometer; Fig. 2, a diagram of a modified arrangement; Fig. 3, a view showing the use of the galvanometer to close regulating or other circuits, and Fig. 4 a view of the indicating-lamp.

1 2 are main conductors of a system of electric lighting, and *a a* electric lamps connected across them in multiple arc circuits 3 4. A is a lamp similarly connected, and similar in every way to the other lamps, except that it has a piece of platinum, *b*, placed between the limbs of its incandescent conductor, while a wire, 5, attached to said platinum, is sealed in the glass of the globe with the wires 3 4. The wire 5 leads to the binding-post *c*, while a wire, 6, connected with the positive wire 3 of the lamp, leads to the binding-post *c'*. These binding-posts are the terminals of a galvanometer which consists of coils *d d* and a needle, *e*, carried by a torsion-wire, *f*. The parts are held in a frame, B. The upper cross-bar of the frame is split at *g*, the split being held to-

2886

gether by screws *h h*, and the torsion-wire is attached to the smooth stud *i*, which is held by friction in the split, its torsion being adjusted by turning the thumb-nut *j*. A spring, *k*, is attached to the other end of the torsion-wire, serving to keep said wire stiff, and the tension of the spring is adjusted by means of nut *l*. A pointer, *m*, extends from the needle to indicate its variations upon a scale, *n*. The torsion of the wire *f* is so adjusted as to hold the needle and the pointer centrally with a normal current—that is, when the lamps of the system are at their normal candle-power—and, as previously explained, any variations in the electro-motive force of the system causing changes in the candle-power of the lamps will produce deflections of the galvanometer-needle, which deflections will be indicated on the scale.

Instead of simply causing the variations to be indicated on the scale, a circuit-controlling arm, *o*, Fig. 3, may be carried by the needle, which may close circuit at contacts *p*, or in any other suitable manner to electrical devices for automatically regulating the electro-motive force of the system, to electrically-operated indicating devices, or to any electrically-operated apparatus.

For regulating a dynamo-electric machine, a mechanism such as shown in my Patent No. 287,524 may be used, the lamp A and galvanometer of the present apparatus being used in place of the pressure-magnet B of said patent, the working-magnets C C of said patent being located in the two circuits, closed by arm *o* of the present apparatus, which takes the place of the armature-lever of said pressure-magnet B. An adjustable resistance, C, may be placed in circuit with the lamp A, to maintain said circuit at the standard lamp-resistance.

In Fig. 2 a lamp, A', is shown placed in a shunt around the lamp A. The lamp A being constantly in use, lamp A' is occasionally placed in circuit instead, so by observing its candle-power it may be determined whether or not the resistance of the lamp A has changed.

What I claim is—

1. The combination of an incandescent electric lamp, a circuit including the vacuous space within the globe of said lamp, and electrical apparatus controlled by the current in such circuit, substantially as set forth.

2. The combination, with a system of electrical distribution, of an indicating or regulating apparatus therefor, comprising a standard lamp, a circuit including the vacuous space within the globe of said lamp, and electrical apparatus controlled by the current in such circuit, substantially as set forth.

3. The combination, with an incandescent electric lamp of a circuit having one terminal in the vacuous space within the globe of said lamp, and the other in connection without the lamp with one side of the lamp-circuit, substantially as set forth.

4. The combination, with an incandescent electric lamp, of a circuit having one terminal in the vacuous space within the globe of said lamp, and the other in connection without the lamp with the positive side of the lamp-circuit, substantially as set forth.

5. The combination, with an incandescent electric lamp, of a circuit having one terminal in the vacuous space within the globe of said lamp, and the other connected with one side of the lamp-circuit, and electrically controlled or operated apparatus in said circuit, substantially as set forth.

6. The combination, with an incandescent electric lamp, of a piece of conducting material placed in the vacuous space within its globe, and a conductor connected therewith and passing through and sealed in the glass of the lamp, substantially as set forth.

7. In a system of electrical distribution, the combination, with incandescent electric lamps connected in multiple arc, of a similar lamp similarly connected, a circuit having one terminal in the vacuous space within the globe of said lamp, and the other connected with one side of the lamp-circuit, and electrically-operated apparatus in said circuit, substantially as set forth.

8. The combination, with an incandescent electric lamp, of a piece of conducting material placed between the sides of the incandescent loop, and a conductor leading therefrom to the exterior of the lamp, substantially as set forth.

This specification signed and witnessed this 2d day of November, 1883.

SPACE TELEGRAPHY.

No. 879,532. Specification of Letters Patent. Patented Feb. 18, 1908

Application filed January 29, 1907. Serial No. 354,662.

To all whom it may concern:

Be it known that I, LEE DE FOREST, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented a new and useful Improvement in Space Telegraphy, of which the following is a specification.

My invention relates to wireless telegraph receivers or oscillation detectors of a type heretofore described in my prior Letters Patent Nos. 824,637, June 26, 1906 and 836,070, November 13, 1906.

The objects of my invention are to increase the sensitiveness of oscillation detectors comprising in their construction a gaseous medium by means of the structural features and circuit arrangements which are hereinafter more fully described.

My invention will be described with reference to the drawings which accompany and form a part of the present specification, although it is to be understood that many modifications may be made in the apparatus and systems herein described without departing from the principles of my invention.

In the drawings, Figure 1 represents in diagram a wireless telegraph receiving system comprising an oscillation detector constructed and connected in accordance with the present invention and Fig. 2 represents a space telegraph receiving system including a modified form of oscillation detector connected therein in a manner which constitutes one of the subjects matter of said invention.

V I, E is an elevated conductor system including the elevated conductor V, earth connection E, and primary I, of the transformer M, the secondary I, of which forms part of the tuned receiving circuit I, C. It will be understood of course that the aforesaid tuned receiving circuit may be associated with the elevated conductor system in any suitable manner.

D represents an evacuated vessel, preferably of glass, having sealed therein three conducting members, F, *a* and *b*, in Fig. 1 and F, *a'* and *b* in Fig. 2. The conducting member or electrode F is shown as consisting of a filament, preferably of metal, which is connected in series with the battery A or other source of electrical current of sufficient strength to heat said filament, preferably to incandescence. The conducting member *b*, which may be a plate of platinum, has one end brought out to the terminal 3. Interposed between the members F and *b* is a grid-shaped member *a*, which may be formed of platinum wire, and which has one end brought out to the terminal 1. The local receiving circuit, which includes the battery B, or other suitable source of electromotive force, and the signal indicating device T, which may be a telephone receiver, has its terminals connected to the plate *b* and filament F at the points 3 and 4 respectively. The means for conveying the oscillations to be detected to the oscillation-detector, are the conductors which connect the filament F and grid *a* to the tuned receiving circuit and, as shown, said conductors pass from the terminals 2 and 1 to the armatures of the condenser C.

I have determined experimentally that the presence of the conducting member *a*, which as before stated may be grid-shaped, increases the sensitiveness of the oscillation detector and, inasmuch as the explanation of this phenomenon is exceedingly complex and at best would be merely tentative, I do not deem it necessary herein to enter into a detailed statement of what I believe to be the probable explanation.

In associating an oscillation detector of the above mentioned type, said detector being now commonly known as the audion, with a closed tuned circuit, it will be noted by reference to Fig. 2, that the secondary I, closes a circuit containing a battery shown at B through the electrode *b*, conducting member *a'* and the conducting gaseous medium intervening between said electrode and member. Also by reference to Fig. 1, it will be seen that a similar closed circuit exists between said battery, and the electrode *b* and conducting member *a*. In order to close each of said circuits to the passage of direct current from the aforesaid battery therethrough, or to prevent the development of a difference of potential between the members *a* and *b*, or between *a'* and *b*, or to prevent the members *a* or *a'* from receiving an electrical charge from said battery, I insert the condenser C' in said otherwise mechanically closed circuit and find that the presence of said condenser produces a great increase in the sensitiveness of the oscillation detector as determined by the very marked increase in the sound produced in the telephone T

evacuated vessel, an electrode inclosed therein, means for heating said electrode, a second electrode inclosed within said vessel, a local circuit having its terminals electrically connected to said electrodes, said local circuit including a source of electromotive force and a signal indicating device, a grid of conducting material inclosed within said vessel and located between said electrodes, and means for conveying the oscillations to be detected to the heated electrode and grid.

14. An oscillation detector comprising an evacuated vessel, two electrodes, one of which is a filament, inclosed within said vessel, means for heating said filament, and a conducting member inclosed within said vessel and interposed between said electrodes.

15. An oscillation detector comprising an evacuated vessel, two electrodes inclosed within said vessel, means for heating one of said electrodes, a grid of conducting material inclosed within said vessel and interposed between said electrodes, a local circuit connecting said electrodes, and a source of electromotive force and signal indicating device in said local circuit.

16. An oscillation detector comprising an evacuated vessel, two electrodes, one of which is a filament, inclosed within said vessel, means for heating said filament, and a grid of conducting material inclosed within said vessel and interposed between said electrodes.

17. An oscillation detector comprising an evacuated vessel, two electrodes inclosed within said vessel, means for heating one of said electrodes, a conducting member inclosed within said vessel and interposed between said electrodes, and a local circuit including a source of electromotive force connecting said electrodes.

18. An oscillation detector comprising an evacuated vessel, two electrodes inclosed within said vessel, means for heating one of said electrodes, a grid of conducting material inclosed within said vessel and interposed between said electrodes, a local circuit including a source of electromotive force connecting said electrodes and a signal indicating device associated with said local circuit.

19. An oscillation detector comprising an evacuated vessel, two electrodes, one of which is a filament, inclosed within said vessel, means for heating said filament, a grid of conducting material inclosed within said vessel and interposed between said electrodes and a local circuit including a source of electromotive force connecting said electrodes.

20. An oscillation detector comprising an evacuated vessel, two electrodes inclosed therein, means for heating one of said electrodes, a conducting member inclosed within said vessel, a closed oscillation circuit, a circuit connecting one element of said oscillation circuit with one of said electrodes and said conducting member, and a condenser in said circuit.

21. An oscillation detector comprising an evacuated vessel, two electrodes inclosed therein, means for heating one of said electrodes, a conducting member inclosed within said vessel, a closed oscillation circuit, a circuit connecting one element of said oscillation circuit with one of said electrodes and said conducting member, a condenser in said circuit, a signal indicating device and a circuit connecting said device with the other of said electrodes and said conducting member.

In testimony whereof, I have hereunto subscribed my name this 21st day of Dec 1906.

The Thermionic Vacuum Tube and its Applications

By H. J. Van Der Bijl, M.A., Ph.D., M.Am.I.E.E.,M.I.R.E., Mem. Am. Phys. Soc., Scientific & Technical Adviser, Dept. of Mines & Industries, Union of South Africa, Late Research Physicist, American Tel. & Tel. Co. and Western Electric Co., New York. First Edition. McGraw-Hill Book Company, Inc., New York, 239 West 39th Street, London: 6 & 8 Bouverie St., E.C. 4, 1920

If we are concerned only with electrodes that can be heated by passing a current through them we can adopt the practice that lamp manufacturers have been following for the last twenty or thirty years, viz., passing a current through the electrodes to raise them to a higher temperature than they attain during operation, and by baking the bulbs in ovens to as high a temperature as the glass can stand. But thermionic devices of the most commonly employed types also contain electrodes (anode and grid) which cannot be heated by passing a current through them. These electrodes can be heated during evacuation by electron bombardment; that is, by passing a thermionic current from cathode to anode through the tube. The amount of this current and the voltages applied should be higher than the values used when the tube is subsequently put in operation. Although these tubes operate under the condition that gas has no influence on the discharge, the operation of the tube will always be better understood if the effects of small traces of gases are known. These effects are therefore discussed in Chapter V.

The thermionic valve (by this we mean a two-electrode thermionic tube) is still used at the present time as a rectifier of alternating current, and as such it is a valuable instrument, and is capable of performing useful functions. Its operation and some of its uses are discussed in Chapter VI.

As a detector of electromagnetic waves, the valve has no commercial value. The device which is used for detecting [fol. 2893] purposes is the three-electrode tube which in addition to the anode and hot cathode, also contains a grid to control the flow of electrons from cathode to anode. The grid was inserted by de Forest in 1907, who called the device the "Audion" and it is the insertion of the grid which has

made the thermionic tube of such great value. Since the flow of electrons from filament to anode or plate can be varied by applying potential variations to the grid, the circuit in which this tube is used consists of two branches: the output circuit connecting the filament to the plate through a current or power indicating device and the input circuit connecting the filament to the grid through the secondary of a transformer or other means of supplying potential variations to the grid.

The audion was first used as a radio detector but was subsequently found to be capable of performing a number of other important functions. In fact, the insertion of the grid into the valve resulted in a device of tremendous potentialities—one that can justly be placed in the same category with such fundamental devices as the steam engine, the dynamo and the telephone.

Since a mere variation in the potential of the grid produces a variation in the plate current, it could reasonably be expected that more power would be developed in the output circuit than the power expended in the input circuit, and this has actually been found to be the case. The operation of the tube as an amplifier is simpler than its operation as a detector. I have therefore found it best first to discuss the manner in which the tube operates as an amplifier, reserving its operation as detector for discussion in a later chapter. Chapter VII not only describes the amplifier and the manner in which it operates, and the circuits that can be used, but also discusses the characteristics of the three-electrode tube.

Since the power in the output circuit of the audion tube is greater than the power expended in the input, it is possible to increase the degree of amplification by feeding back part of the energy in the output to the input. If the proportion of the energy thus returned to the input circuit is large enough and the phase relations of the currents in the output and input circuits are right, the tube can be made to produce sustained oscillations. What is usually done is to connect the tube in an oscillation circuit having the desired capacity and inductance, and then couple the output circuit to the input in such a way that current variations in the output circuit cause potential variations to be impressed on the grid. There are a great variety of circuits whereby this can be accomplished. To make a three-electrode tube produce sustained oscillations is an extremely simple matter,

but to make it operate in the most efficient way as an oscillation generator requires a knowledge of the various factors that influence its operation as such. These matters are discussed in Chapter VIII.

When the tube is used as an amplifier or oscillation generator it is desirable that the characteristic representing the relation between the plate current and the potential of the plate or grid be as nearly linear as possible. On account of the negative space charge of the electrons in the space [fol. 2894] between filament and anode the characteristic is not linear, but convex towards the axis of voltage. When the applied voltage becomes sufficiently high to attract the electrons over to the plate as fast as they are emitted from the filament, the characteristic curve becomes concave towards the voltage axis and finally becomes nearly horizontal, thus giving the saturation current. In order to obtain the best operation of the tube as an amplifier, it is necessary to straighten out the characteristic of the plate circuit. Means whereby this can be done are discussed in Chapter VII. The curvature of the characteristic causes the shape of the current wave in the output to be distorted, and is therefore a very undesirable feature of the audion as an amplifier. On the other hand, the fact that the characteristic is curved simply increases the number of uses to which the audion can be put. Its ability to detect electromagnetic waves lies in the curvature of its characteristic. This also makes it possible to use the tube for modulating high frequency waves for the purpose of radio or carrier telephony and telegraphy. The processes involved in detection and modulation are identical, and these are therefore treated together in Chapter IX.

In Chapter X are described a few miscellaneous applications of the thermionic tube. This list is intended to exemplify the manner of applying the principles of the tube and does not make any pretense at being complete. It is believed that the number of such applications is destined to increase considerably and that the tube will become of increasing importance not only in engineering practice, but also in university and college laboratories.

A large number of names have been used to designate the three-electrode type of thermionic tube, such as audion, pliotron, triode, thermionic valve, etc.—an impressive array of names which certainly attests the importance of this device. To forestall any possible confusion in the mind of

the uni-tiated reader I may say that these names all apply to one and the same thing, namely the audion or three-electrode tube discussed in the following pages.

The major portion of the development of the audion has taken place in the past eight years, but while the number of applications of the tube increases almost daily, we must frankly admit that as far as the tube itself is concerned, it was developed to a full grown and powerful instrument as early as 1914. The rapid development of this device, both in the United States and Europe and the popularity it has gained, are due to a number of factors that have concurred to place it in the foreground. One obvious reason of course, is its ability to perform such a large number

. . . . . .

Referring now to Fig. 12, it is seen that there is a definite frequency ν_0 of the light at which the voltage necessary to drive the electrons back becomes zero. This means that for frequencies lower than this value no electrons escape at all. Putting $V=0$ in equation (21) we get:

$$\nu_0=\frac{\epsilon}{h}\Phi \qquad (22)$$

[fol. 2895] This limiting frequency, commonly referred to as the *photo-electric long wave length limit* is a fundamental property of solids and, is equal to a constant multiplied by the electron affinity—the same constant that plays such an important part in the emission of electrons from hot filaments in the thermionic vacuum tube.

The quantities h and ϵ are universal constants, that is, their values are independent of the matter under investigation and the conditions of the experiments. Their values are $h=6.55\times10^{-27}$ erg. sec., and $\epsilon=4.77\times10^{-10}$ E.S. units.

22. *Control of Space Current by Means of an Auxiliary or Third Electrode.*—A convenient and what has proved to be a very valuable means of varying a space current is obtained by placing a third electrode in the neighborhood of the cathode and applying potential variations to it. This scheme was used by de Forest to control the electron discharge in his audion detector in 1907.[1] He later gave the

[1] Lee de Forest, U. S. Patent No. 841387, 1907.

auxiliary electrode the form of a wire gauze or grid placed in the path of the discharge between cathode and anode.[2] About the same time von Baeyer[3] also used an auxiliary electrode to control a thermionic current from a hot filament. In von Baeyer's arrangement the anode was a cylinder and the cathode a wire placed along its axis. The third electrode was a wire gauze bent into the form of a cylinder and placed between cathode and anode. A similar scheme was also used by Lenard[4] in 1902 in connection with photo-electric experiments. It is hardly necessary to say that the insertion of the grid has made the audion a device of immense practical importance and enabled it to perform functions that would otherwise have been impossible.

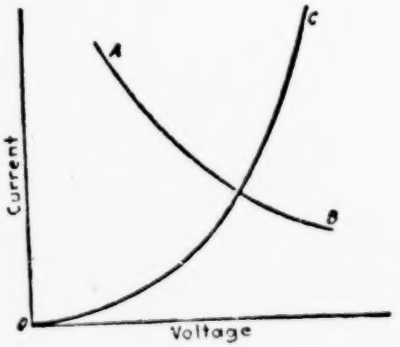

FIG. 34

tic"; that is, its relation between current and voltage is given by a curve such as AB (Fig. 34). The gas-free device, on the other hand, has a characteristic similar to OC. The difference between tubes containing these characteristics becomes apparent when we consider the corresponding a-c. resistances. The a-c. resistance for small current or voltage variations at any definite voltage is given by the reciprocal of the slope of the characteristic at a point corresponding to that voltage. Since the slope of the curve AB is negative, the arc has a negative resistance, while the resistance of a gas-free tube is positive.

It is the negative resistance of the arc which enables it to produce sustained oscillations. It will be shown in Chapter VIII that a device containing only two electrodes can only produce sustained oscillations if it has a negative resistance or a falling characteristic. The principle involved in the production of sustained oscillations by the audion or three-[fol. 2896] electrode thermionic tube is entirely different

and depends on the controlling action of the grid on the electron flow from filament to anode.

* * * * * * *

radio detector. The circuit in which Marconi used this device as a radio detector is shown in Fig. 39.

45. *Valve Detector with Auxiliary Anode Battery.*—By our present standard of measurement the two-electrode tube is a very inefficient detector. It can be, and has been used more efficiently by operating on a chosen point of the current-voltage characteristic, thus making it fall in the class of rectifiers given by condition (4) instead of that represented by condition (3). This can be done by inserting a local battery in the circuit as shown in Fig. 40.[5]

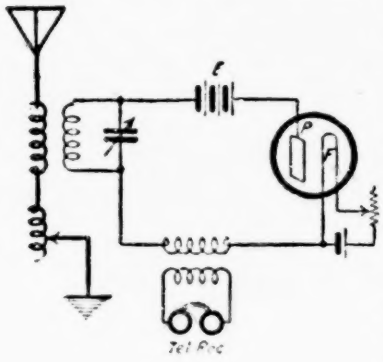

FIG. 40

The operation of the device when used this way can be understood from the following: By the insertion of the battery E there is established in the circuit FPE a constant direct current which has a finite value even when no oscillations are impressed from the antenna. The current through the device can therefore be represented by a function of the form

$$I_{(+i)} = f(E + e \sin pt), \qquad (5)$$

where E is the local source of direct voltage, I the direct current due to E and i the superposed a-c. due to e. This can be expanded into a powerseries.

$$f(E + e \sin pt) = f(E) + f'(E)\, e \sin pt + f''(E) \cdot \frac{e^2 \sin^2 pt}{2} + \cdots + f^{(n)}(E) \frac{e^n \sin^n pt}{n} \cdots$$

Chapter VIII—The Vacuum Tube as an Oscillation Generator

79. *Introductory.*—Since the three-electrode tube can operate as an amplifier, the energy in the output circuit is greater than that in the input circuit. Hence, if part of the energy in the output be returned to the input, there will — a further amplification of energy resulting in an increased output. If the amplified energy gets back to the input in sufficient amount, and if the phase relations of the output and input currents are right, there will be a constant re-amplification and feeding back of energy from the output to the input, and the device will then produce sustained oscillations without it being necessary to supply potential variations to the grid by external means. In other words, the device will then operate as an oscillation generator. [fol. 2897] The frequency of the oscillations will be determined by the constants of the circuit, while their intensity will depend on the amount of energy fed back to the input, the shape of the characteristic curve, and the rate at which power is dissipated. There is a variety of circuit arrangements whereby this can be done. These circuits can all be divided into three main groups in which part of the energy in the output is returned to the input: (1) by resistance coupling, such as is explained, for example, in connection with Fig. 145, page 259; (2) inductive coupling; (3) capacitative coupling between output and input.

In the present chapter we shall briefly discuss the conditions that must be satisfied in order to use the three-element tube to produce oscillations of a definite frequency and amplitude. A large amount of work has been done on this phase of the subject, and no attempt will be made here to enter into a full discussion of these investigations. It is believed rather that an explanation of the fundamental principles that govern the production of sustained oscillations with the three-electrode tube, and an indication

* * * * * * *

From this we see that in order to obtain sustained oscillations from a device having only two electrodes, it is necessary that the device shall have a negative resistance. Examples of negative resistances have already been given in the previous pages. Thus an arc may have a negative resistance, its characteristic being of the form shown by the

curve AB in Fig. 34. The resistance is given by the slope of the characteristic and this is a negative quantity for a characteristic of the kind shown. Fig. 16, page 48, shows another characteristic which over a region ABC has a negative slope and is obtained as the result of the emission of electrons from metals under the impact of electrons. Such characteristics as these are sometimes referred to as "falling characteristics."

The thermionic valve does not show a falling characteristic like the curve AB of Fig. 34, when it is sufficiently well evacuated to prevent the effects of ionization by collision from appreciably influencing the discharge. The characteristics of thermionic valves are those given and discussed in the previous chapters and it will be seen that for such devices the resistance is always positive. It is, therefore, impossible to obtain sustained oscillations from a well-evacuated thermionic valve containing only two electrodes. If such a device contains an appreciable amount of gas during the operation, the characteristic becomes unsteady and sometimes, especially at the higher voltages, exhibits regions over which the slope is negative, and when operated over that region it is, of course, possible to obtain sustained oscillations. The condition which makes this possible in a two-electrode device is unfortunately due to the cause which makes such a device unsatisfactory; namely, the presence of too much gas in the device, thus causing unsteadiness of the discharge and making reproducibility practically impossible. If a controlling electrode or grid be added to the two electrodes of a valve, the operation becomes different and we now have a device which can produce sus- [fol. 2898] tained oscillations with facility while at the same time satisfying all the conditions that are necessary to secure satisfactory operation in every respect, namely, freedom of gas with consequent steadiness and reproducibility of results, and comparatively long life.

82. *Condition for Oscillation for Three-Electrode Tube.*— Let us now consider a circuit like that shown in Fig. 152. This is one of a large number of possible oscillation circuits. It is

DEFENDANT'S EXHIBIT M

Proceedings of Physical Society of London, Vol. XXII, September 1910

XXV. On ~~an~~ Oscillation Detector actuated solely by Resistance-temperature Variations. By W. H. Eccles, D.Sc.[1]

In a recent communication to the Physical Society[2] the properties of a type of iron-oxide coherer were discussed. The paper described experiments on coherers made by dipping a slightly oxidised iron wire into clean mercury, or by pressing a fine iron wire against a thinly oxidized iron plate, and the results were discussed mathematically. It was shown that in the case of the iron point and oxidized plate the whole of the experiments could be explained qualitatively on the assumption that the only electrical phenomena at play were the Joule effect and the resistance-temperature changes in the small mass of oxide between the metal electrodes. The hypothesis that was put forward must be summarized here. Let z be the resistance of that part of the detector where the current flow is so constricted that the Joule effect produces rise of temperature, and r the resistance of the remainder of the circuit. The resistance z is usually localized at the contact of the conductors that form the detector, and it varies with the temperature of the minute mass of matter at the contact; let a be the coefficient of decrease of resistance with rise of temperature. The resistance r includes that of the bulk of the substances forming the detector, the leads and the telephone; it is supposed constant. Let c be the current when the electromotive force applied to the detector is e. Assume that the rate of loss of heat from the warmed contact is $m\theta$, where θ is the temperature of the contact above that of the surroundings. Then it was shown that in the steady state

$$e=\left(\frac{\rho_0}{1+q\alpha\theta^2}+r\right)c, \qquad (1)$$

[1] Read May 27, 1910.

[2] W. H. Eccles, "On Coherers," Phil. Mag. June 1910; Proc. Phys. Soc. vol. xxii. 1910.

where ρ_0 is the resistance of the contact when cold and q is a constant. If the curve $\epsilon = \rho_0 c / (1 + q\alpha c^2)$ be plotted with c as abscissæ and ϵ as ordinates, it is seen to rise from the origin of coordinates with an increasing gradient till at a definite value of c it becomes vertical. Then as c increases, the curve bends towards the axis of c and approaches it asymptotically. Along this latter part of the curve, increasing current is associated with decreasing elec- [fol. 2899] tromotive force—an unstable state of affairs. Any conductor possessing a negative temperature-coefficient of resistance exhibits these properties. In such conductors an increase of current produces, in accordance with Joule's law, an increase of temperature, and consequently, a diminution of the resistance. The curve shows that after a certain stage is passed the diminution of the resistance which accompanies increasing current is great enough to lead to a catastrophe. Stability can, however, be obtained by introducing into the circuit of the variable resistance ρ a sufficiently large constant resistance r. The phenomenon resembles that of the electric arc. The unstable portion of the above curve corresponds, in fact, to the "falling characteristic" of the arc.

If the resistance r is large the ϵ, c curve has a positive gradient throughout, and the gradient has a maximum at some value of ϵ. Near this point the contact is found to work best as a detector of oscillations. The hypothesis put forward by the author supposes that a train of oscillations, by yielding its energy as heat to the contact, raises the temperature there and disturbs the existing equilibrium of current and voltage. The dissipation of a train of oscillations is accomplished in a time of the order of a fifty-thousandth of a second; the ensuing fluctuation of the current causes the sound in the telephone. In the paper cited, the energy w given to the telephone circuit was shown to be connected with the energy W delivered by the train of waves by the equation

$$w = m(W - a), \qquad (2)$$

where m and a are constants for any fixed value of the current. This theoretical conclusion agreed well with the experiments on an iron oxide coherer. The object of the present paper is to show that the above hypothesis holds good for a very different type of detector. All the well-known forms of "contact" detector consist of a contact between two substances that stand well apart in the thermo-

electric series, and the thermoelectric force plays a very important part in their operation. They are usually classed as "rectifying detectors" to distinguish them from such detectors as the coherers. In seeking a "rectifying detector" that would illustrate the above hypothesis, substances that stand far apart in the thermoelectric series must be avoided, for such substances would introduce Peltier effects that would tend to mask the resistance-temperature phenomena we wish to isolate. Even in the iron : iron-oxide : iron coherer it is possible that thermoelectric forces arise owing to unequal heating of the two iron to iron-oxide junctions. It occurred to me, therefore, to construct a detector out of one substance only. Accordingly a search was made for a substance possessing high, but not too high, resistivity, with large negative temperature-coefficient. Several such substances were found among the native crystalline oxides and sulphides. Most of these are allotropic, and must on that account be avoided. Fortunately galena, the native sulphide of lead, has fairly high resistivity, a very large negative resistance coefficient, and crys- [fol. 2900] tallizes in the cubic system. A galena-galena detector was therefore constructed. Two pieces of galena cut from the same crystal were embedded in solder, mounted in a clamp, and brought into gentle contact. It was put into a wireless telegraph receiving set and was found to yield excellent signals when a current of proper magnitude was passed through it.

A few preliminary experiments showed that it was not easy to find two pieces of galena, which when placed together and submitted to positive and negative voltages in turn, exhibited perfect symmetry. The symmetry is always small, and is probably due to the rise of thermoelectric forces at the contact when it becomes heated by the steady current, and these forces are probably caused by slight variations in the chemical composition of the galena from point to point in the crystal. When a contact that gives symmetrical voltage-current curves is found, it constitutes a detector that operates only when a current is passing through it. The efficiency of the detector is the same for each direction of the current, and appears to be practically independent of the shape of the galena surfaces at the contact.

The experiments now to be described were made on selected galena-galena combinations in precisely the same

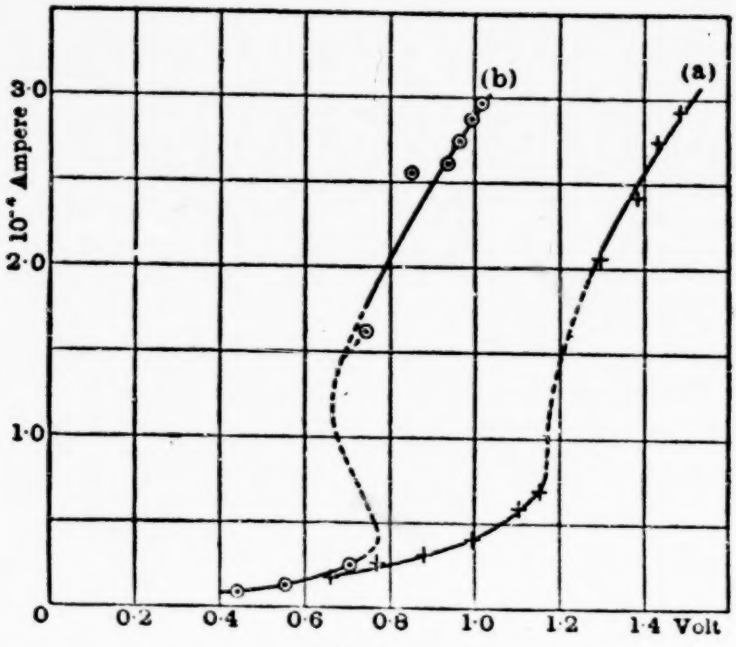

FIG. 1

way as the earlier experiments on the iron-oxide detectors. The diagram of the apparatus employed is shown in fig. 1 of the previous paper (Phil. Mag. June 1910, p. 872, & Proc. Phys. Soc. vol. xxii; p. 293). The mutual inductance between L and L′ was 2500 cm. in obtaining the results described below.

[fol. 2901] The detector was placed at D and submitted to an electro-motive force from P_2, which was varied in steps from zero to about one volt positive or negative. At each step an observation was made of the steady current through the detector, and of the intensity of the sound produced in the telephone by electrical oscillations of amplitude fixed by the position of the jockey on P_1. The steady current observation was made by means of a shunted galvanometer kept connected in series with the telephone. The intensity of the sound was

DEFENDANT'S EXHIBIT N

Wireless Telegraphy with Special Reference to the Quenched-Spark System

By Bernard Leggett, A. M. I. E. E., late Wireless Technical Staff, Messrs. Siemens Bros. and Co., Ltd., Late Officer in Charge of Trench Wireless, 1st Corps, B. E. F. London, Chapman & Hall, Ltd., 11 Henrietta St., W. C. 2, 1921

increase of the e. m. f. causes the passage of a current. Such increase may be due to a signal received upon an aerial and the passage of the current of the external e. m. f. is rendered audible by the telephone.

For good working the negative electrode should be a point of about .002 sq. mm. surface. These detectors are extremely sensitive, but require accessory regulating apparatus and attention, and are now largely replaced by contact detectors.

4. *Contact detectors.*—These are the detectors most used at the present day. They consist essentially of contact points between a suitable metal and crystal such as molybdenite or galena. Such a contact has the property of allowing oscillatory currents to pass in one direction and not the other, so rendering them aperiodic. The passage of these aperiodic currents may be heard by connecting a small condenser in circuit and shunting it with a telephone wound to the correct high resistance.

These detectors are the most sensitive for ordinary working, cannot be greatly damaged, are always ready for use, and require no auxiliary apparatus. They are therefore very widely used.

The action of Crystal Detectors.—Very many hypotheses have been put forward to explain the action of contact detectors, the chief views being that the phenomena depends on thermo-electric properties, photo-chemical properties, electrolysis in solids, electro-static attraction, etc.

The balance of evidence would seem to be that their action depends on electro-thermal phenomena. Such phenomena depends on:

1. The variation of resistance with temperature.

2. The Peltier effect, which may be expressed as the causation of an increase or decrease of temperature, when

an electrical current passes across a junction of two *different* metals. Conversely a current is generated when such junction undergoes a variation in temperature (made use of in the thermo-couple).

[fol. 2902] 3. The Thomson effect, which produces an electrical e. m. f. between different parts of the same metal at different temperatures.

Any or all of these phenomena appear to cause rectification of the oscillatory currents of wireless telegraphy. The elaborate consideration of these effects is primarily a matter of pure physics, and for further information the reader must be referred to Starling's Electricity and Magnetism."

The application of such phenomena to wireless reception is Boltzmann in 1890, would appear to be the first to apply gaseous tubes to wireless purposes, i. e. to detect Hertzian oscillations.

Zehnder, in 1892, improved Boltzmann's arrangement producing his "trigger-tube" (Fig. 72 (1)), in which a local circuit (F.E.G.) was so adjusted that its potential was just insufficient to break down the resistance of a gaseous tube. Complete breakdown resulted when a small additional potential was supplied by an Hertzian oscillator, represented by ABCD. The apparatus was used purely to detect the presence of oscillations, but was undoubtedly also an intensifying arrangement.

Whilst it was not thermionic, i. e. it did not utilise electrons given off from a heated filament, it is undoubted more allied to the present-day amplifier in its method of operation than the later two-electrode tube of Fleming.

In 1884, Edison, at the Philadelphia Exhibition, had exhibited an apparatus consisting of a plate between the limbs of the filament of an incandescent lamp (Fig. 72 (2)). He showed that if a galvanometer was connected between the plate and the negative end of the filament no current was shown, whereas when the plate and the positive end of the filament were connected, a current was obtained.

Since electrons had not yet been shown to exist no reason could be given for this effect, called the Edison effect, but which had also been independently shown in high vacua, by Elster and Geitel.

Fleming, in 1904, utilised the Edison effect, and Elster and Geitel's apparatus in a modified form, to produce a

wireless detector, rectification being brought about owing to the unidirectional conduction already mentioned. Fleming's arrangement is shown in Fig. 72 (3), and is in effect a reversal of the relative position of plate and filament in Edison's apparatus.

The Fleming valve was purely and simply a rectifier or detector. In no way was it an intensifying device, it did not use a very high vacuum, as is the case in the modern valves of Langmuir and Meissner, and was not a means of generating oscillations like these later valves.

Whilst Fleming must be credited as being the first to apply thermionic phenomenon to wireless detection, the claim that he is alone the originator of the present-day thermionic valve is rather exaggerated, since the intensifying properties of the present-day valve are far more important than its detecting properties, and as an intensifying arrangement, the Zehnder "trigger-tube" is more akin to the modern valve in principle.

[fol. 2903] As a detector the Fleming valve was fairly sensitive, but from the author's own personal experience, a result also noticed by Stanley, it was not so sensitive as a crystal detector. As well as being more sensitive, the crystal detector has the advantage of not requiring any heating battery, with consequent adjustment and maintenance troubles.

The next step in the development was due to de Forest who was the first to use the modern three-electrode valve for wireless work in his "Audion" patent of 1907. This arrangement (Fig. 72 (4)) is essentially the modern valve. It had a vertical filament, a zig-zag grid and a plate, and was certainly a great advance.

As far as the author can ascertain, and certainly from his patent specification, this valve did not, like some of his later ones, use an oxide coated filament. It was a vacuum tube but not of exceeding high vacua. De Forest would appear to have intended his device as a detector only, and did not recognise its possibilities as an intensifier, which it must undoubtedly have been.

Much controversy and litigation occurred over the patent aspects of the audion, Fleming claiming that it infringed his two-electrode valve, although he himself states "the Audion differs from the author's oscillation valve in having a grid and a plate sealed into the bulb, in place of a single metal cylinder surrounding the filament."

The result of this American litigation was that, whereas de Forest was prevented from using his valve, since it infringed Fleming's patent, on the other hand the Marconi Company, who were interested in Fleming's action, were equally prevented in using de Forest's three-electrode valve, which according to de Forest ("Electrician," p. 26, 1916) was their intention.

De Forest's letter referred to above should certainly be read before forming any opinion as to the relative value of claims regarding the origin of the valve. It certainly illustrates how patent litigation can retard scientific progress.

The whole situation regarding this controversy is best summed up in Mr. Justice Sargeant's words at the Chancery Division, on Fleming's application for extension of his 1904 patent: "I should hesitate to describe a three-electrode valve or de Forest valve as being a mere improvement in view of the great independent invention displayed in that device. I do not think that the valve would ever have come into being but for the previous invention of the 1904 Fleming valve, though it is of course obvious and admitted by the Petition, that where the de Forest

It will be most convenient to deal with each class of generator separately, before dealing with purely telephonic questions.

Arc-generators

In 1899 Mr. W. Duddell found that if a direct-current electric arc, such as that of an arc-lamp, is shunted by a circuit containing capacity C and inductance L (Fig. 180), [fols. 2904-2905] oscillations of a frequency, approximately

$$\frac{1}{2\pi\sqrt{LC}},$$ occur in the shunt circuit.

The production of these oscillations is as follows:

On closing the shunt circuit, the flow into the condenser causes a drop in the flow of current into the arc. Consequently the temperature falls, and the resistance of the arc increases, becoming a greater fraction of the resistance of the main circuit. The resistance of the main circuit and the difference of potential between the arc carbons rises with a further production of flow into the condenser. Eventually

the accumulation of charge in the condenser raises the difference of potential between its plates to that between the carbons. This results in stopping the flow into the con-

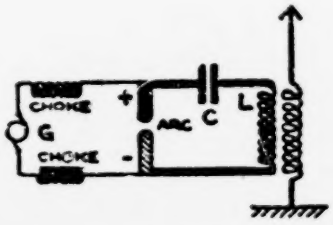

FIG. 180.—Duddell arc.

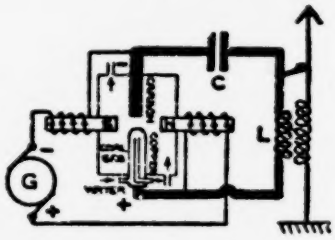

FIG. 181.—Poulsen arc.

denser, and the arc regains its original condition. When the current via the arc has risen to its original value, its resistance falls, and in consequence the potential across the arc falls. The condenser then begins to discharge across the arc, so reversing the previous condition.

The inductance in the shunt circuit gives this circuit inertia so that the current having started, the circuit is always carried past the stable condition and oscillations occur. The existence of the oscillation depends upon the fact that the resistance of the arc varies with the current in such a manner that the potential difference between the carbons diminishes with increasing current, and the arc behaves as though it had a negative resistance.

No. 781,001. Patented January 31, 1905.

UNITED STATES PATENT OFFICE.

PETER COOPER HEWITT, OF NEW YORK, N. Y., ASSIGNOR, BY MESNE ASSIGNMENTS, TO COOPER HEWITT ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

MEANS FOR AMPLIFYING ELECTRICAL VARIATIONS.

SPECIFICATION forming part of Letters Patent No. 781,001, dated January 31, 1905.

Application filed May 16, 1902. Serial No. 107,804.

To all whom it may concern:

Be it known that I, PETER COOPER HEWITT, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented certain new and useful Improvements in Means for Amplifying Electrical Variations, of which the following is a specification.

In certain patents granted to me September 17, 1901, attention is called to the fact that the resistance of an inclosed vapor or gas carrying current in an electric circuit varies inversely with the current carried by the vapor. Accordingly if a varying potential be applied to an apparatus of the general character described in the patents referred to a variation of current will take place in the inclosed gas or vapor, and this variation of current will affect the entire circuit in which the apparatus is included, and if the circuit is so arranged that the gas or vapor apparatus shall represent a considerable portion of the total resistance of the circuit the variations of current thus caused in the conducting gas or vapor will cause comparatively large variations in the entire circuit.

It is customary to operate electric circuits for various purposes by causing variations of potential in the circuit, such variations being utilized to influence appropriate receiving apparatus. In the present invention I avail myself of the peculiar features of electrical resistance in a gas or vapor conductor to vary or magnify the effects produced by potential variations in a circuit. By virtue of the described characteristics of gas or vapor conductors it is possible, for instance, to translate variations of potential in a circuit into variations of current or quantity, and inasmuch as the conducting gas or vapor responds practically instantaneously to the applied variations of potential, currents of any practical rapidity or frequency can be made to undergo the described transformation and produce their effects upon a suitable receiving apparatus. As the practical result of an increase of applied potential is an increased flow of current, the original electrical impulses in the circuit may produce magnified effects as compared with those which the same impulses would produce if applied directly to the receivers.

The drawing herewith is a diagram of a typical circuit embodying my invention.

In the drawing, 1 is a suitable source of current supplying a circuit 2. Included in the circuit are a transmitting or potential-changing apparatus 3 and a receiving apparatus 4. The transmitting apparatus may be a telegraph-relay, a telephone-transmitter, or any other device adapted to vary the potential of the current in the circuit 2. The receiving apparatus 4 may be any suitable receiver adapted to respond to variations of current in the line.

A circuit made up as described is common enough in the electrical arts. The improvement forming the subject of the present application consists in causing the described circuit to be affected by the peculiar action of an inclosed gas or vapor apparatus, (shown at 5.) This apparatus may be such an apparatus as described in my patents above referred to as a "gas" or "vapor" electric lamp, or it may be an apparatus generally similar to such a lamp, but having no light-giving quality by reason of being specially adapted to the purposes of this invention without regard to the matter of light. For this purpose the device may be made with a comparatively short gas or vapor path and having such cross-section that with the current normally traversing it the vapor or gas may become but faintly luminous. The resistance of the circuit outside the device 5 is practically constant except for the slight variations introduced through the instrumentality of the potential-changing apparatus 3. As the resistance of the device 5 varies substantially inversely with the quantity of the current flowing, or, to put it another way, requires a definite voltage to pass a definite current therethrough, any diminution, for instance, of the potential applied to its terminals by reason of an increase of resistance on the part of the device 3 will result in not only the diminution of flow of current due to the

2908

increased resistance of the device 3, but also to an additional diminution due to the change brought about in the device 5 by the decreased current resulting from the decreased potential at the terminals of the device 5. Likewise an increase of potential at the terminals of the device 5, due to a change of resistance in the outside circuit, will cause an increase of current-flow therethrough greatly in excess of the change due to the change of resistance in the other portions of the circuit. In other words, the changes of resistance in other portions of the circuit than the device 5 bring about such variations of conditions in the device 5 as to augment the variations of current-flow through the entire circuit. It should be borne in mind, however, that the resistance of the other portions of the circuit than the device 5 serves in a measure as a balancing resistance for the device 5; otherwise a decrease of resistance in the external circuit might result in a continuing unchecked decrease of the total resistance of the circuit including the device 5. The device 5 itself, however, has in a measure a self-corrective tendency within certain limits, due to internal variations of resistance resulting from changes in its temperature. The temperature of the device 5 must be taken into consideration when measuring the device for ohmic resistance, as its ohmic resistance varies with the temperature which is brought about by variations in the flow of current and also by the surrounding conditions. The method of controlling these is set forth in the patents hereinbefore referred to. The variations in the amount of current through which the device 5 may be made to operate may be made quite wide by constructing it with the required heat-radiating capacity. It will now be understood that the receiving apparatus 4 will be affected by a comparatively large current and will respond with greater certainty and effectiveness than it otherwise would. The same amplification of the effects of potential changes in the circuit takes place whatever be the degree of potential increase or variation.

When the resistance of the element 5 is made a considerable portion of the total resistance of the circuit, the effect of the changes of resistance in the element named will be very marked, especially when the source of supply is great.

By reason of the gaseous condition of the conducting medium employed the gas or vapor apparatus responds instantly to potential changes in the current without essential loss of energy. In this respect it differs from other materials or substances, because in such other materials or substances work has to be done in the process of reducing the resistance whereby a loss of energy is caused and the time element becomes a considerable factor, while in my apparatus the amount of material so affected is so small that the energy required to produce the result may be practically neglected.

Means for starting the flow of current through the apparatus are set forth in the patents hereinbefore referred to.

I claim as my invention

1. The combination in an electric circuit, of a source of potential variation, a receiving apparatus adapted to translate the variations caused by the source, and an inclosed gas or vapor conducting medium.

2. The combination in an electric circuit, of a source of potential variations, a receiver adapted to respond to changes of current in the circuit, and a quickly-responding inclosed gas or vapor conducting medium whose resistance decreases with increments of temperature.

No. 781,009. Patented January 31, 1905.

UNITED STATES PATENT OFFICE.

PETER COOPER HEWITT, OF NEW YORK, N. Y., ASSIGNOR, BY MESNE ASSIGNMENTS, TO COOPER HEWITT ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

METHOD OF AMPLIFYING ELECTRICAL VARIATIONS.

SPECIFICATION forming part of Letters Patent No. 781,009, dated January 31, 1905.

Application filed May 16, 1903. Serial No. 157,805.

To all whom it may concern:

Be it known that I, PETER COOPER HEWITT, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented certain new and useful Improvements in Methods of Amplifying Electrical Variations, of which the following is a specification.

In certain patents granted to me September 17, 1901, notably in the patents numbered 682,695, 682,696, and 682,697, attention is called to the fact that the resistance of an inclosed vapor or gas carrying current in an electric circuit varies inversely with the current carried by the vapor. Accordingly if a varying potential be applied to an apparatus of the general character described in the patents referred to a variation of current will take place in the inclosed gas or vapor, and this variation of current will affect the entire circuit in which the apparatus is included, and if the circuit is so arranged that the gas or vapor apparatus shall represent a considerable portion of the total resistance of the circuit the variations of current thus caused in the conducting gas or vapor will cause comparatively large variations in the entire circuit.

It is customary to operate electric circuits for various purposes by causing variations of potential in the circuit, such variations being utilized to influence appropriate receiving apparatus. In the present invention I avail myself of the peculiar features of electrical resistance of a gas or vapor conductor to vary or magnify the effects produced by potential variations in a circuit.

By virtue of the described characteristics of gas or vapor conductors it is impossible, for instance, to translate variations of potential in a circuit into variations of current or quantity, and inasmuch as the conducting gas or vapor responds practically instantaneously to the applied variations of potential currents of any practical rapidity or frequency can be made to undergo the described transformation and produce their effects upon a suitable receiving apparatus. As the practical result of an increase of applied potential is an increased flow of current, the original electrical impulses in the circuit may produce magnified effects as compared with those which the same impulses would produce if applied directly to the receivers.

The drawing herewith is a diagram of a typical circuit embodying my invention.

In the drawing, 1 is a suitable source of current supplying a circuit 2. Included in the circuit are a transmitting or potential changing apparatus 3 and a receiving apparatus 4. The transmitting apparatus may be a telegraph-relay, a telephone-transmitter, or any other device adapted to vary the potential of the current in the circuit 2. The receiving apparatus 4 may be any suitable receiver adapted to respond to variations of current in the line.

A circuit made up as described is common enough in the electrical arts.

The improvement forming the subject of the present application consists in causing the described circuit to be affected by the peculiar action of an inclosed gas or vapor apparatus, (shown at 5.) This apparatus may be such an apparatus as described in my patents above referred to as a "gas" or "vapor" electric lamp, or it may be an apparatus generally similar to such a lamp, but having no light-giving quality by reason of being specially adapted to the purposes of this invention without regard to the matter of light. For this purpose the device may be made with a comparatively short gas or vapor path and having such cross-section that with the current normally traversing it the vapor or gas may become but faintly luminous. The resistance of the circuit outside the device 5 is practically constant except for the slight variations introduced through the instrumentality of the potential-changing apparatus 3. As the resistance of the device 5 varies substantially inversely with the quantity of the current flowing, or, to put it another way, requires a definite voltage to pass a definite current therethrough, any diminution, for instance, of the potential applied to its terminals by reason of an increase of resistance on the part of the de-

vice 3 will result in not only the diminution of flow of current due to the increased resistance of the device 3, but also to an additional diminution due to the change brought about in the device 5 by the decreased current resulting from the decreased potential at the terminals of the device 5. Likewise an increase of potential at the terminals of the device 5 due to a change of resistance in the outside circuit will cause an increase of current-flow therethrough greatly in excess of the change due to the change of resistance in the other portions of the circuit. In other words, the changes of resistance in other portions of the circuit than the device 5 bring about such variations of conditions in the device 5 as to augment the variations of current-flow through the entire circuit. It should be borne in mind, however, that the resistance of the other portions of the circuit than the device 5 serves in a measure as a balancing resistance for the device 5. Otherwise a decrease of resistance in the external circuit might result in a continuing unchecked decrease of the total resistance of the circuit including the device 5. The device 5 itself, however, has in a measure a self-corrective tendency within certain limits due to internal variations of resistance resulting from changes in its temperature. The temperature of the device 5 must be taken into consideration when measuring the device for ohmic resistance, as its ohmic resistance varies with the temperature which is brought about by variations in the flow of current and also by the surrounding conditions. The method of controlling these is set forth in the patents hereinbefore referred to. The variations in the amount of current through which the device 5 may be made to operate may be made quite wide by constructing it with the required heat-radiating capacity.

It will now be understood that the receiving apparatus 4 will be affected by a comparatively large current and will respond with greater certainty and effectiveness than it otherwise would.

The same amplification of the effects of potential changes in the circuit takes place whatever be the degree of potential increase or variation.

When the resistance of the element 5 is made a considerable portion of the total resistance of the circuit, the effect of the changes of resistance in the element named will be very marked, especially when the source of supply is great.

By reason of the gaseous condition of the conducting medium employed the gas or vapor apparatus responds instantly to potential changes in the current without essential loss of energy. In this respect it differs from other materials or substances, because in such other materials or substances work has to be done in the process of reducing the resistance, whereby a loss of energy is caused and the time element becomes a considerable factor, while in my apparatus the amount of material so affected is so small that the energy required to produce the result may be practically neglected.

Means for starting the flow of current through the apparatus are set forth in the patents hereinbefore referred to.

I claim as my invention—

1. The method of amplifying potential variations caused in an electric circuit, which consists in applying the said variations to a quickly-responding medium in the circuit, thereby causing a change in current-flow through such medium, and by such change of current-flow producing in such medium a change of specific resistance resulting in a still further change in current-flow through the circuit.

2. The method of amplifying energy variations caused in an electric circuit of which an inclosed gas or vapor forms part, and of translating the effects of such amplified variations, which consists in affecting the conducting gas or vapor by variations of current, transforming such variations of current into variations of resistance, and applying such currents to a suitable translating device.

3. The method of amplifying energy variations caused in an electric circuit including an inclosed conducting gas or vapor and electrodes therefor, which consists in affecting the conducting gas or vapor by variations of current, and thereby transforming such variations into corresponding amplified variations of current.

Signed at New York, in the county of New York and State of New York, this 9th day of May, A. D. 1902.

The Principles Underlying Radio Communication

Radio Pamphlet No. 40, December 19, 1918, Signal Corps, U. S. Army. Washington, Government Printing Office, 1919

to be used for large distances. In this factor, λ enters in such a way as to make the received current less when the wave length is short than when it is long. Hence, in general, we conclude that to get the greatest possible received current, we should use short waves for short distances and long waves for long distances.

It may be seen from the formulae that, for simple antennae, the received current (for a given wave length, sending current, receiver resistance, and distance apart) is greater, the greater the heights of the antennae. In the case of closed-coil aerials under the same conditions, the received current is greater the larger the areas and the number of turns of the coils. For the dimensions actually used, antennae are much more effective radiators and receivers than closed coils. In order to secure the same radiation or received current with a closed coil as with an antenna, other conditions being the same, its dimensions must be made nearly as great as the antenna height. However, it is often possible to put more current into a transmitting coil than into the corresponding antenna, and also the resistance of a receiving coil is usually smaller than that of the corresponding receiving antenna. Hence the closed coil can be a smaller structure than the antenna.

The closed coil has some other advantages. For a given power input in the transmitter, the closed coil aerial is not at quite such a disadvantage with the ordinary antenna as the formulae show, because a larger fraction of the radiation is sent out in the direction desired. As a receiver, the closed coil has the very great advantage that the direction of the waves it receives can be determined. These points are discussed further in the next chapter.

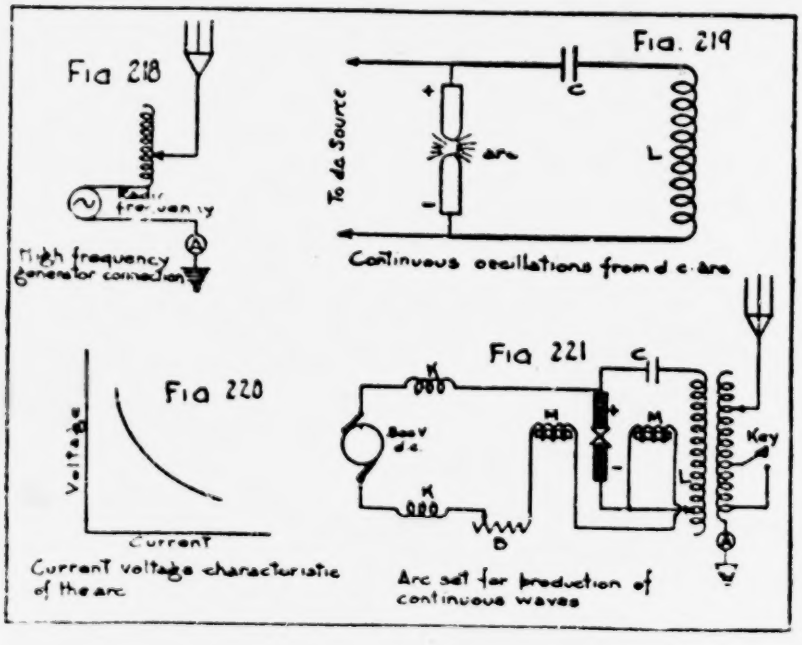
E. Device for Radiating and Receiving Waves

137. *Description of the Antenna.*—The antenna is used in radio communication for two purposes, (1) to radiate elec-

tric waves, and (2) to receive or detect electric waves which come to it. An antenna consists essentially of one or more wires, suspended at some elevation above the earth. When electric waves reach an antenna, they set up an alternating emf. between the wires and the ground, and the longer and higher the wires, the greater the emf. produced. As a result of this emf., an alternating current will flow in the antenna wires. The energy of the current is absorbed from the passing wave, just as some of the energy of a water wave is used up in causing vibrations in a slender reed which stands in its way.

. . . . . .

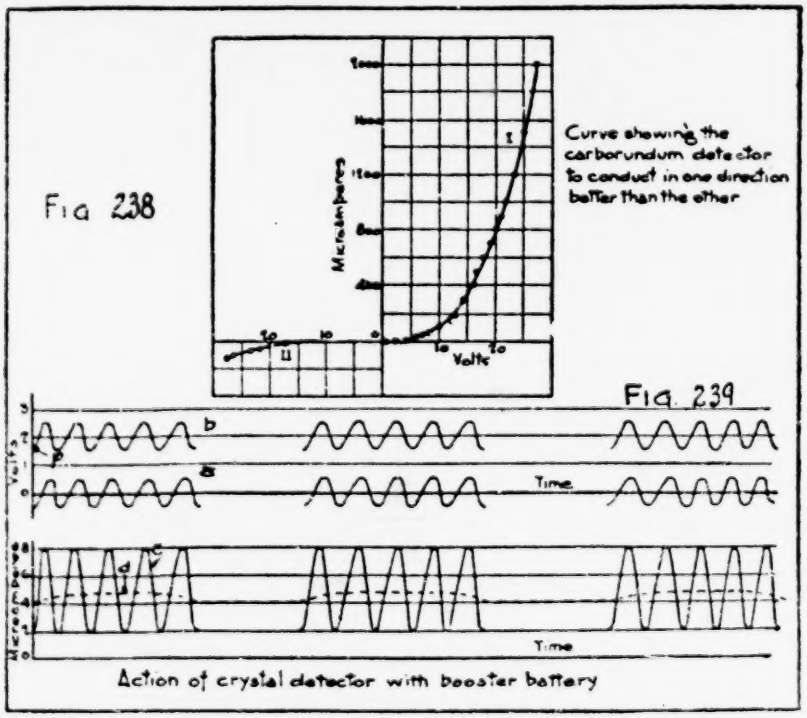
[fol. 2915] frequency can be used. See Section 95. This is connected directly or inductively to the antenna and ground. See Fig. 218. This constitutes the simplest possible connection for producing continuous waves. However, to obtain a wave length as short as 1500 meters, the frequency of the alternating current must be as high as 200,000 cycles per second. The generator speed required to produce this frequency is so high that a special type of construction is needed for such a machine. It is also necessary to have apparatus for keeping the speed constant, so that the wave



length will not change (since $f\lambda_m = 300{,}000{,}000$). This method is not available for generating very short waves; for these, the oscillating vacuum tube is used. See Section 198.

174. *Arc Sets.*—A much used method for producing undamped waves of rather great wave length is by means of a d. c. arc operated on about 500 volts. It has been discovered that an electric arc between proper electrodes shunted by an inductance coil and a condenser will produce undamped oscillations through the shunt circuit. The connection is shown in Fig. 219. The operation is as follows.

[fol. 2916] Fig. 238 shows a current-voltage characteristic curve for carborundum in contact with a metal. The current flows much more readily in one direction than in the other under equal but opposite emfs. For example, under a constant impressed emf. of 10 volts in one direction a current of 100 microamp. is obtained, while with the voltage reversed the current is only 1 microamp. This illustrates the property of "unilateral conductivity," or rectification. Furthermore, as regards the second property, when the



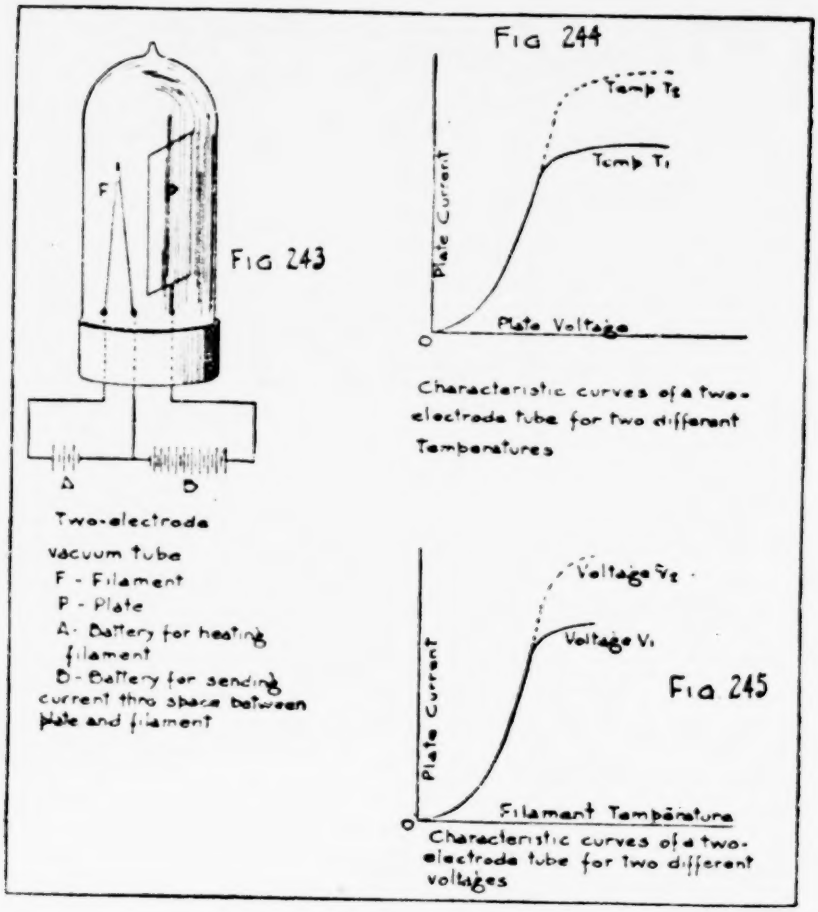
voltage is applied in the direction giving the larger current, the conductivity (ratio of current to voltage) increases as

the voltage increases. This is shown by the right hand portion of the figure. The characteristic curve of any ordinary metallic conductor would be a straight line.

Booster Battery.—In order to make use of the second property namely the bending of the current-voltage characteristic, a local or "booster" battery is inserted in series with the crystal. Using the battery makes the crystal operate at a voltage which corresponds with the sharpest bend of the curve, so that a slight increase of volt-

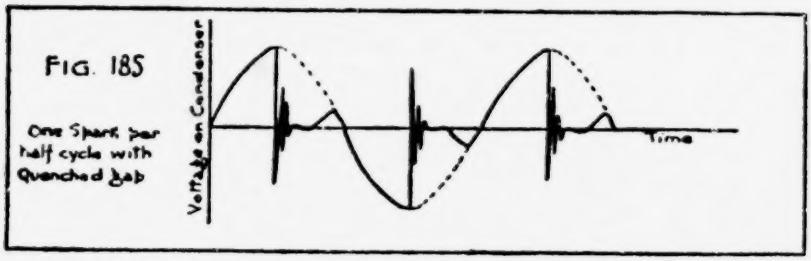
[fol. 2917] the vacuum is very complete. If there is more than the merest trace of gas remaining in the tube, the operation is more complicated, and a larger current will usually flow with the same applied voltage. This happens in the following manner.

In a rarefied gas, some of the electrons present are constituent parts of atoms and some are free. These free



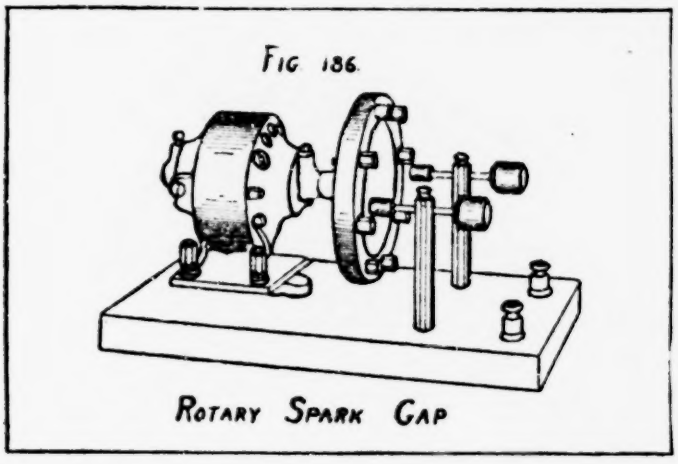
electrons move about with great velocity, and if one of them strikes an atom, it may dislodge another electron from the atom. Under the action of the emf. between plate and filament the newly freed electron will acquire velocity in one direction (that of the colliding electron) and the——

[fol. 2918] This regular occurrence of the discharges gives smooth and efficient operation, and a pure musical tone. The synchronizing is made possible by attaching the rotating element of the spark gap to the shaft of the generator



which charges the condenser. A rotary gap not so timed is called "non-synchronous."

Attempts to produce a high pitch from a 60-cycle source by a synchronous gap giving, say, exactly 6 sparks per half cycle, have not given satisfaction, because the applied voltage is not the same at the time of the different sparks, and



while the note is of high pitch, it is not musical. It has been found better to use a non-synchronous gap in such a case, producing a large number of sparks per second and letting them occur wherever they may happen——

[fol. 2919] DEFENDANT'S EXHIBIT T

Principles Underlying Radio Communication, 1922

175. *The Characteristics of the Direct-Current Electric Arc.*—If between two pieces of conducting material, such as two carbon rods, separated in air by a short distance, there is applied a considerable d.c. voltage, an arc will be formed between the carbon electrodes and will continue if a sufficient voltage is maintained. The voltage required to maintain the arc will be much less than that required to start the arc cold, and, in fact, an arc is not usually started with the electrodes separated. If we study the behavior of such an arc and measure the current corresponding to various d.c. voltages maintained at the terminals of an arc already formed, we will obtain a curve for voltage plotted against current like that shown in Fig. 223. This curve shows that as the applied voltage is increased the current through the arc decreases. The corresponding characteristic curve of an ordinary ohmic resistance would be a straight line sloping upward to the right from the origin. This behavior of the arc, exactly opposite to what occurs when the voltage applied to an ordinary conductor is increased, is described by saying that the arc has a "falling characteristic," or that it is a variable resistance, which increases as the applied voltage increases. It is this "falling characteristic" of the arc that makes possible its use as a generator of undamped oscillations.

When the arc is used to generate undamped oscillations the current which flows at any instant between the arc electrodes is the resultant of the steady current supplied by the d.c. generator and the current in the condenser shunt circuit, as described in the next section. In the first two cases described in the next section, which can properly be considered to be arc discharges, the current between the electrodes always flows in the same direction, but may vary in magnitude.

The statement is sometimes made that an arc is a "negative resistance"; this statement can not be considered correct. The current in an arc passes from the electrode of higher voltage to

[fol. 2920] The production of this effect is, however, subject to certain conditions. The arc A must be formed by the electromotive force of a secondary battery or other steady generator, and a resistance, R (see Fig. 81), must be placed in series with it. The inductive resistance L placed a shunt to the arc must be a low resistance—generally speaking, something less than 1 ohm. The condenser C employed should be one suitable for high potential, as although the impressed electromotive force on it is only 50 volts, the action of resonance (see Chap. III) creates a potential difference between its plates, which at moments rises to several hundred volts, and hence a thin paper condenser may break down.

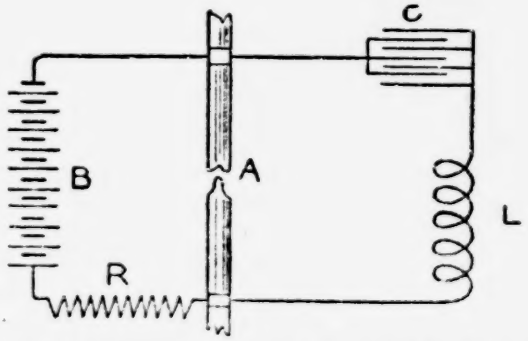


Fig. 81.—Arrangements for producing Duddell's Musical Arc. B, battery; R, resistance; A, carbon arc; C, condenser; L, inductance.

One explanation put forward as an explanation of this effect on its discovery was that it essentially depends upon the existence of a *negative resistance* in the arc, and that the frequency which can be obtained is limited by the arc itself. We shall present the outlines of this theory first, as proposed by Mr. Duddell and supported by some others.

Suppose a small instantaneous change dV, is made in the potential difference of the electrodes, whether carbon or metal, between which the arc is formed, and let the corresponding small change in the current through the arc be denoted by dA. Also let the resistance of the inductance in series with the condenser be represented by r. The theory advocated by Mr. Duddell is that the conditions for the production of high frequency alternating currents

. . . . . .

It has been shown by the author that even then the oscillations are not quite continuous.[1] The oscillating arc tends to break up into a series of intermittent discharges, and it is somewhat difficult to obtain absolutely unbroken undamped oscillations. Some interesting investigations were carried out in the author's laboratory in 1907 by Mr. W. L. Upson, on the characteristic curves of electric arcs between various electrodes and in different gases.[2] These experiments showed that for an arc taken between a carbon (negative) and a water cooled copper (positive) electrode the characteristic curve is much steeper at and about the same arc current, than for the carbon-carbon arc in air (see Fig. 86). Hence it is clear that one element in Poulsen's discovery is [fol. 2921] the effect of hydrogen or hydrocarbon vapour in steepening the characteristic curve of the direct current arc. The reason for this has not yet been fully explained.

Poulsen immediately applied the above method for producing undamped electric oscillations in radiotelegraphy, with the cooperation of P. O. Pedersen.[3]

We shall return again, in Chap. VIII. on radiotelegraphic stations, to the consideration of the practical use of Poulsen's discovery and apparatus in wireless telegraphy and telephony.

Meanwhile the reader's attention may be drawn to one or two other points in connection with the production of electric oscillations by the arc.

Much light has been thrown on the nature of the phenomenon by the careful researches of Professor H. Th. Simon.[4] He has studied by means of the oscillograph and Braun vacuum tube, the form of

Wireless Telegraphy and Telephony

A Handbook of Formulae, Data and Information. By W. H. Eccles, D.Sc., A.R.C.S., M.I.E.E., Professor of Applied Physics and Electrical Engineering at the City and Guilds of London Technical College, Finsbury. Honorary Secretary of the Physical Society of London and of the British Association Committee for Radiotelegraphic Investigations. Second Edition, Revised and Enlarged, 1918

(a) The maximum value of the oscillatory current may be so much less than the steady current that the arc is not extinguished. This is the case of the musical arc first described fully by Duddell.

(b) The discharge current from the condenser may be so large as to extinguish the arc at an instant near the maximum of the oscillatory current. This includes the usual case of the Poulsen arc.

[4] See H. T. Simon, "The Dynamics and Hysteresis of the Electric Arc," *Phys. Zeitschrift*, vol. 6, p. 297, 1905, or *Science Abstracts*, vol. 8A, *abs.* 1465; also "Theory of the Singing Arc," *Phys. Zeitschrift*, vol. 7, p. 433, 1906, or *Science Abstracts*, vol. 9A, *abs.* 1423.

(c) The oscillatory current may, after extinguishing the arc, kindle it in the direction opposite to the steady current. [fol. 2922] This is exemplified by the quenched spark with the "ordinary" spark as an extreme case. They have been discussed in the preceding pages.

Case *a.—Condenser Current Less than Arc Current.*— The first type of arc generator, which gives nearly pure sine oscillations of feeble intensity, has had no application. The greatest rates of conversion of direct current energy into oscillatory energy are reached within acoustic limits of frequency.

The ability of an arc to sustain oscillations in a shunt circuit depends on the fact that in the circumstances in which it is used, an increase of current through the arc involves a decrease of the voltage at its terminals, and vice versa. The curve connecting i and e with values of i as abscissae is called the "characteristic" curve of the arc; it has a negative gradient. Suppose the condenser-inductance circuit applied suddenly as shunt to an arc supplied with a constant current i_0. The condenser begins to charge, robs the arc of current, the arc voltage therefore rises, and the condenser charges still further. A limit to the voltage is reached when the condenser current stops increasing, for then the steady current through the arc starts increasing, the voltage falls and the condenser begins to discharge more or less in the time of oscillation determined by L and C. The condenser discharge current now adds to the steady current through the arc, makes the arc terminal voltage lower than the normal, and encourages the motion of the electricity, which goes on till the condenser is fully charged in sign opposite to the last occasion. The process plainly goes on indefinitely. The arc thus acts somewhat like the slide valve of a single-acting steam engine, since it automatically admits electricity at a pressure above normal into the capacity and withdraws it at a lower pressure than normal, work being done on each occasion. In Fig. 130 let PN represent the normal voltage, ON the corresponding current, of an arc with a falling characteristic. Then QM represents the condenser current and QN the voltage of the condenser terminals at a certain instant during the

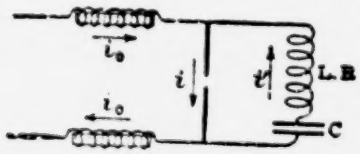

Fig. 129.

oscillatory charging, and M′ refers to an instant during discharge. Assuming that the oscillations follow a sine law, and that they are of the natural period of the circuit, then since v and i are in phase the work done per second in the shunt-circuit is $\frac{1}{2}IV$ where I is the amplitude of the current, V of the voltage, of the shunt-circuit. This work may be regarded as all spent in a resistance R in the circuit, or partly in a coupled circuit, and thus

$$\tfrac{1}{2}IV = \tfrac{1}{2}RI^2$$
$$R = V/I.$$

that is,

[fol. 2923] If R exceeds this value the oscillation will not be sustained. Thus, the average negative gradient, which is V/I, or QQ′÷(MQ+Q′M′), must not be less than R. For infinitesimal oscillations this may be written

$$R < -\frac{dv}{di},$$

which is sometimes called Kaufmann's condition.

H. T. Simon first made clear that the characteristic curve of Fig. 130 is not followed exactly during rapid oscillations: during reduction of current a lower curve during augmentation of current a higher curve, is followed. (See Case *b*.) Being a time effect, this has no analogy with hysteresis, though sometimes given that name in error. This "dynamic characteristic" for *a* type oscillations is indicated in Fig. 131.

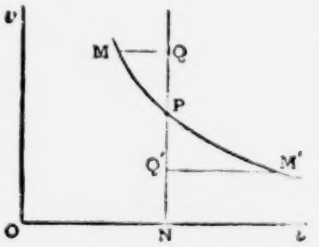

Fig. 130.

W. Duddell has given the following details of a musical arc: Carbons solid, Conradty, 9 mm. diameter, arc length 1·5 mm., arc current 3·5A, steadying resistance 42Ω, shunt inductance 5·3mH, resistance of inductance and leads 0·41Ω capacity of condenser 1·1 to 5·4μ F, R.M.S. current through condenser 3A when capacity is 5·4μ F, voltage of battery 50V.

Case *b*.—*Condenser and Arc Currents Nearly Equal.*—The second type of arc generator, the Poulsen arc, gives very energetic oscillations at frequencies up to two or three millions per second, and is used in the Poulsen system of wireless telegraphy (see "Systems"). In order to make the

FIG. 131.—Dynamic characteristic of arc oscillations.

characteristic steep and allow of the use of high voltages, it is advantageous to form the arc between carbon and copper electrodes, with the copper as the positive pole, in an atmosphere of hydrogenous vapour (Fig. 132). The desired periodic extinction of the arc is assisted by strongly cooling the electrodes and by forming it in a strong perpendicular magnetic field, but is governed largely by the relative magnitudes of condenser and inductance. Kiebitz states that when the inductance is too small (the product LC being of assigned value) the arc is very sensitive to changes in the supply of voltage, the frequency of the oscillations varies

. . . . . .

Although a great many investigators have attempted to give the rationale of the Poulsen arc, it was not until very recently that even an approximate understanding of its operation was attained. P. O. Pedersen points out that many early investigations are vitiated by the fact that the arc as set up in laboratories for investigation has usually been working under conditions different from those of the [fol. 2924] Poulsen arc as used in practice. He calls the practical size of arc the "normal Poulsen arc." Such an arc is one with at least 10 to 15 amperes direct current, and with, for example a value $\sqrt{L/C} = 50$ ohms at wave length 1,000 m. In the normal arc the arc is extinguished and ignited every period of the oscillation, and the ratio of the effective oscillatory current to the steady feeding current is $1/\sqrt{2} = 0.707$. Such an arc gives maximum efficiency of conversion when the voltage across it is the least possible, and for this a definite gap and a definite magnitude of field are required, whose values depend on the constants of the circuits. The arc will maintain oscillations for adjustments of gap slightly different from the optimum and great latitude in magnetic field is possible if the normal condition has not to be maintained. According to Barkhausen, the connection between current and voltage at the arc during oscillation is as follows: The arc burns for the greater part of the oscillation at a steady voltage, while the current rises and falls when the voltage reaches a very low value the arc expires suddenly, and the voltage falls to a low negative value in common with the condenser it then rises, while the current

is still zero, to a high value, perhaps tenfold the burning value, and the arc is ignited; immediately the current is established the voltage falls to the burning value and remains practically steady while the current rises and falls in the oscillation. Barkhausen's view is that the high ignition voltage is the essential element in the efficient working of the Poulsen arc, and that the hydrogenous atmosphere and the magnetic field operate by enhancing the ignition voltage. Pedersen's experiments contradict this view as regards the normal Poulsen arc, through supporting it to some extent if the gap is much too long for normal. In the normal arc, in fact, the ignition voltage is not very high, and the efficiency of the normal arc is brought about almost entirely by the high value of the voltage rise that occurs at the *extinction* of the arc, which was disregarded by Barkhausen. This rise of voltage at extinction has been shown previously to exist in the case of the musical arc by A. Blondel using his oscillograph, and it is now shown to be of paramount importance in the radiofrequency arc by Pedersen's oscillograms obtained with Gehrcke's cathode glow oscillograph. It is, no doubt, the consequence of the negative gradient of the arc characteristic.

With the correct arc gap and the correct strength of magnetic field, the oscillogram of the current through the arc is an almost complete sine-wave with small sections cut away from the troughs near the maximum negative point, and the voltage rises and falls sharply at the extinction, and also at the ignition, point without becoming negative at any time. The arc is struck on or near the edges of the electrodes, is driven outwards by the magnetic field, is extinguished at the extreme position and ignites afresh at the edges, the process being repeated with great regularity in each

Discussion on Thermionic Values. W. H. Eccles, "The Three-Electrode Thermionic Vacuum Tube and the Revolution in Wireless Telegraphy"

During the war dark hints reached the civilian that a revolution was taking place in wireless telegraphy, the

principal agent in which was reported to be an instrument called a "valve", a "lamp", or a "tube." This instrument seemed to have risen suddenly into a predominant position among all the apparatus of the wireless experimenter and operator, and appeared to be of use in every corner of his outfit. The complete name of the instrument is the three-electrode thermionic vacuum tube. It must be emphasised that it is the three-electrode valve, and not the valve with two electrodes, that has been responsible for the overthrowing of the old methods and apparatus. That it has been a veritable revolution can be seen by comparing the common practice in wireless telegraphy of 1914 with that of 1919. In 1914 practically all the most powerful transmitting stations in the world generated waves by sparks, and signals were received at nearly all stations by means of crystal detectors or magnetic detectors. The spark method of generating waves involved the use of very large antennæ for spanning great distances; and at receiving stations which wished to listen to stations

Journal of the Institution of Electrical Engineers, including original communications on telegraphy and electrical science

Published under the supervision of the editing committee and edited by W. G. McMillan, secretary. Vol XXX. 1900-01. London: E. and F. N. Spon, Limited, 125, Strand, W.C. New York: Spon and Chamberlain, 12, Cortlandt Street. 1901

On rapid variations in the current through the direct-current arc

By W. Duddell, Wh. Sc., Associate

It may be thought by some that the title of this paper is rather contradictory in that there should not be any variation in the current through a direct-current arc. I will therefore explain at once that I simply use the term "direct-current" as implying that the current is supplied by cells or by a direct-current dynamo, and not as implying that the

current is necessarily constant in value. It may also be as well to state that by *Arc* I do *not* mean *Arc Lamp*, as all the effects to be described are quite apart from those produced by regulating mechanisms.

The effect of varying the current through the direct-current arc very slowly, so slowly in fact that the carbons have time to burn into shape corresponding to each value of the [fol. 2926] current, has been investigated by many experimenters, but it is to Mrs. Ayrton [1] that the honour belongs of giving a complete investigation of all that occurs when any of the variables in the direct-current arc are changed in any way. The other extreme, namely, very sudden changes in the current, has also been investigated by Mrs. Ayrton,[2] thus leaving a gap in the experimental evidence as to what occurs between very slow variations and isolated sudden changes in the current.

The present paper is an attempt partly to fill this gap by giving an account of what occurs when the current is periodically varied more or less rapidly over a range which is very small compared with the mean value of the direct current.

The current through a direct-current arc supplied with power from any circuit may vary either owing to changes taking place in the circuit, such as variations in E.M.F. or resistance, or owing to effects in the arc itself, such as hissing, humming. Although any variation in the current naturally entails a corresponding change in the arc itself, it will, I think, be found convenient to classify the observed effects according to whether the primary cause of the variation is in the arc or in the circuit which supplies it.

Part I

Cause of the Variation of the Current in the Circuit Supplying the Arc

The effects of varying the current may be divided under four heads, viz., the effect on the P.D. between the terminals of the arc, on the light emitted, on the shape of the craters, and on the vapour column. These will be considered in order. I shall assume in all cases in Part I. that the ampli-

---

[2] *The Electrician*, 1895, vol. xxxiv., pp. 471, 541.

tude of variation of the current from the mean is small, generally much less than 10 per cent, and that the arc experimented on is neither hissing nor humming.

Effect on the Potential Difference Produced by Variations of the Current

If the current varies very slowly, then the relation between the P.D. current and length is that given by Mrs. Ayrton's curves. Directly the rate of variation is increased so that the carbons have not time to burn into shape, corresponding with the instantaneous values of the current, the relation will be changed, and it is conceivable that *if* the rate of variation were high enough and the amplitude small enough, the conditions of the arc would in no way be changed, so that the ratio of the change in P.D. to the corresponding change in current, would be a constant and equal to the true resistance of the arc. I shall show later that this assumption, which is the basis of several experiments on the resistance of the arc, notably those by Messrs. Frith and Rodgers,[2] requires a much higher rate of variation of current than they employed.

[fol. 2927] One of Mrs. Ayrton's curves, contained in a letter by Prof. Ayrton to *The Electrician*,[3] illustrates very well how the connection between the P.D. and current depends on the rate of variation of the latter. This curve shows that the *first* effect of *suddenly increasing the current* through a cored-solid arc[4] is to cause a *transient rise in the P.D.* between the terminals; the effect of a *slow increase of current* being, as is well known, to produce a *decrease in the P.D.* This first transient rise in the P.D. which was obtained with a cored-solid arc, was also, I believe, obtained with a cored arc, but I am unaware of its having been observed for a solid arc.

Thinking that this might be due, as pointed out by Prof. Ayrton, to the extreme quickness of the phenomenon when

[2] *Proceedings of the Physical Society*, 1896, vol. xiv, p. 307.

[3] *The Electrician*, 1896, vol. xxxvii, p. 321.

[4] "Solid", "solid-cored", and "cored" are mean, respectively are between two solid carbons, between one solid and cored, and between two cored carbons; the top or + electrode being always placed first.

both carbons were solid, I tried to record the transient rise in P.D. for the solid arc by means of an oscillograph, the sudden increase of the current being obtained by discharging a condenser through the arc. This experiment was successful, and a transient rise in P.D. was observed, *the P.D. and current increasing together, but only for about* 1/5000 *second*. At the end of this very short time the P.D. decreased with an increase of current in the ordinary way.

If it can be assumed that during this first 1/5000 second the conditions of the arc are not changed, then the solid arc has a positive resistance, contrary to the results obtained by Messrs. Frith and Rodgers, and it is at any rate evident that, had the frequency of their superimposed alternating current between 5,000 ~ per sec. instead of 250 ~ per sec., the sign of the resistance as obtained by them would have changed, though I do not say that even at that frequency its true value would have been obtained. In any method for measuring the resistance of the solid arc which depends on the change in the P.D. produced by a change of current, these changes must, therefore, take place in less than 1/5000 sec. in order not to allow the arc conditions to change; results to be described later indicate a still shorter time.

I will not, however, pursue this subject any further, as it would unduly extend the length of this paper to include a description of a complete series of experiments on the resistance of the arc which I have recently completed.

Effect on the Light Emitted Produced by Variations of the Current

It is well known that the light of the arc varies when the current is changed, though how small and rapid the variation in current may be and yet produce a perceptible change in the light does not seem to have been investigated. Professor Fleming and Mr. Petavel [6] and Mr. Burnie [7] have determined the instantaneous values of the light and current in the case of alternate-current arcs, and have found that [fol. 2928] the variation in light roughly follows the variation of the current; the maximum luminous intensity occurring about 1/1000 sec. later than the maximum current.

[6] *Proceedings of the Physical Society*, 1896, vol. xiv, p. 115.

[7] *The Electrician*, 1897, vol. xxxix, p. 846.

Herr Görges[5] has also noticed that the variations in the current due to the teeth on the armature of a dynamo produced an appreciable variation in the light at the rate of 300 per second.

In order to test how rapid and how small a variation of the current from the mean could be detected in the light of the direct-current arc, I arranged an arc so that its image as seen through a central slit parallel to the carbons was projected on to a rapidly falling photographic plate, the instantaneous value of the current being recorded simultaneously on the same plate by means of an oscillograph. The small quick variations of the current through the arc were produced by passing the oscillatory discharge of a condenser in series with a self-induction through it, so that the arc current consisted of a large constant part on which was superimposed a small ripple which died away after a few oscillations.

By this method I find that in an 8 ampere solid arc a *distinct variation is produced in the light emitted by both the + crater and the vapour column when the amplitude of the variation of the current from the mean is only 3 per cent. and the frequency of these superimposed variations is as large as 1300 ~ per sec.* At this frequency the variation in light became indistinguishable when the amplitude of the variation of the direct current was reduced to 2 per cent.

Owing to the difficulty in estimating the points of maximum density in the band on the plate which represents the light emitted in consequence of the smallness of the variation of the current and therefore of the light, I was unable to be certain whether the maximum light lags behind the maximum current; but if it does, the lag is very slight, not exceeding 1/10000 sec. for an 8 ampere solid arc.

It must be remembered that the above variations of light are those of the actinic rays which affect the photographic plate; the visual rays will probably vary in a similar manner, though possibly not to the same extent.

Effect on the Craters Produced by Variations of the Current

Mrs. Ayrton tells me that she noticed that the variations in the current used by Messrs. Frith and Rodgers, who superimposed an alternating current of 0.5 to 1.0 ampere

[5] *Elektrotechnische Zeitschrift*, 1895, vol. xvi, p. 548.

R.M.S. value, at frequency of 100 ~ per sec. on a 10-ampere direct-current arc, so altered the shape of the ends of the carbons that she could easily distinguish them from normal carbons formed without any variations in the current. I find that if the superimposed alternating current be reduced to 0.1 ampere under the same conditions, the ends of the carbons appear unaffected.

[fol. 2929] Effect on the Vapour Column Produced by Variations of the Current

Sounds

Corresponding with each value of the current through the arc there is probably a definite cross-section of the vapour column, so that if the current varies rapidly through an arc of fixed length, the volume of the vapour will also vary and sound-waves will be given out. This, I believe, is the generally accepted explanation of the humming of the alternate-current arc.

In the case of the direct-current arc, sounds are also emitted even when the variations in the current are very slight. For example, the variation of current caused by the commutator segments of a direct-current dynamo passing under the brushes can be heard in the arc. This variation of the current caused by the commutator segments, even when in good condition, was found by Messrs. Frith and Rodgers[9] in the case of a 5 k.w. two-pole machine to vary between 2.5 and 9 per cent. of the mean current according to the position of the brushes.

Another striking example of how sensitive the arc is to small variations in the current is furnished by the fact that a Wehnelt interrupter, working an induction coil on the direct-current street mains, will cause any arc supplied by the same mains to give out the same noise as the interrupter itself, even when a considerable distance intervenes between the place where the arc is connected with the mains, and where the interrupter and coil are joined on, as observed by Herr Simon,[10] Mrs. Ayrton, and Mr. Jervis Smith.[11]

---

[9] *Proceedings of the Physical Society*, 1896, vol. xiv., p. 307.

[10] *Annalen der Physik und der Chemie*, 1898, vol. lxiv., p. 233.

[11] *The Electrician*, 1899, vol. xliv., p. 16.

It must be clearly understood that the arcs here referred to are normal silent arcs; that is, if they were supplied with a really steady current they would have been practically silent.[12]

In order to determine what variation in the current was necessary to cause the arc to emit a clearly audible note, the current from a high-frequency alternator, kindly lent by Sir D. Salomons, was superimposed on the direct current by the method shown in Fig. 1. The current from the alternator passes through a condenser F, a dynamometer D, and the arc in series; and it is practically prevented from flowing through the cells which supply the arc by the self-induction L. The direct current is prevented from flowing through the alternator by the condenser F.

It was found by this means that a 10-ampere direct current, solid or cored arc, length 3 to 5 mm., would produce a distinct note even if as small a R.M.S. current as 1 1000 ampere, as measured by D, was superimposed on the direct current for frequencies of the added current from a few hundred up to 8,000 ~ per second. Thus a *variation of the* [fol. 2930] *order of 1 part in 10,000 from the mean current will alter the vapour column sufficiently to produce sound-waves.*

Further experiments with another alternator and R.M.S. superimposed currents of 1 20 to 1 10 ampere on a 10-

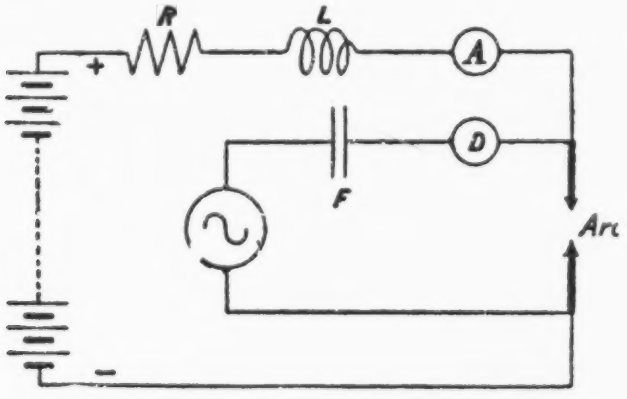

Fig. 1.

[12] Absolute silence is almost impossible, as the least want of homogeneity, or impurity in the electrodes, causes small spits and sounds.

ampere solid arc, proved that the sounds only became inaudible at frequencies approaching 30,000 ~ per second.

At these frequencies I am uncertain whether the arc had really ceased to give a note, as the ear fails to detect sounds of so high a pitch.

This sensibility of the arc for very small changes in its current explains the fact that not only can rapid variations

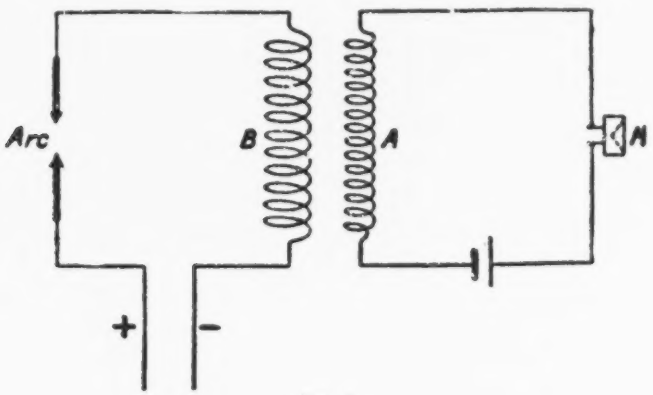

FIG. 2.

of current in any circuit supplied from the same generator as the arc be heard in the arc, but also variations of current which occur in a totally independent circuit supplied by a separate generator can be detected in the arc due to mutual induction between the two circuits.

Arc as a Telephone Receiver

The fact that the arc is sensitive to such small variations in the current and over such a wide range of frequency, at once suggests that the direct-current arc might be used as [fol. 2931] a telephone receiver. This suggestion, which was made in a leader of *The Electrician* in 1899, had already been carried out by H. Simon [13] in 1898.

The method used by H. Simon for superimposing a microphone current on the main arc current is shown in Fig. 2, in which A and B are two coils having mutual induction, and M the microphone. The current through A varies when M is spoken into and induces E.M.F.'s in B, which vary the current through the arc in such a way that it reproduces sounds and even speech distinctly.

---

[13] *Annalen der Physik und der Chemie*, 1898, vol. lxiv., p. 233.

The variation of the current through the arc obtained by this method is not as large as it might be, as the E.M.F.'s induced in B have to send currents round the whole arc circuit, including any steadying resistances, and also through the self-induction in the armature, if a dynamo is used, instead of only through the arc where the varying currents are actually required. I have obtained a better result by replacing the alternator of Fig. 1 with a microphone and mutual induction as shown in Fig. 3. A and B are the two coils of a mutual induction, F a condenser of about two or three microfarads, and L a high self-induction, the object of the self-induction being to prevent the microphone currents flowing around the cells instead of through the arc.

With this arrangement and suitable arc conditions, to be explained later, *the arc will speak sufficiently loudly and clearly to be heard at a distance of 10 to 12 feet in a quiet room.* [Experiment.][14] The sound-waves given out by the arc are, therefore, of such an intensity that when the energy is spread over a spherical surface of 20 feet diameter, the ear placed at any point can hear speech distinctly. It seems probable that if all the energy available could be collected

[14] Note (*added February 1st, 1901*).—As I have had several inquiries from experimenters wishing to repeat this experiment, I append some data of the apparatus actually used at the meeting.

The microphone M was supplied by the National Telephone Company and intended for long distance transmission, two accumulators being used in series with it. The mutual induction A : B consisted of a solenoid 30 cms. long wound with about 1,200 turns of No. 18 D.S.C. wire in six sections having an iron wire core about 15 mm. diameter. Diameter of solenoid over winding = 54 mm. For the experiments 3 sections = 600 turns were used for A, and two sections = 400 turns for B.

Resistance of A = 1.52, of B = 1.53 ohms. Mutual induction 25.3×10^{-3} henrys. Cored carbons were used in the arc, the other data being those given above.

If a suitable mutual induction A:B is not available a self-induction may be used, by connecting the leads from the microphone and cells to the terminals of B instead of those of A, B being now simply a coil having high self-induction and low resistance.

and concentrated on the ear, very powerful sound-sensations might be produced.

The loudness of the sounds given out by the arc is increased by lengthening the arc, as this increases the volume of the vapour column which emits the sounds. It would also seem as if increasing the main current which increases the cross-section of the arc should also be beneficial, but experimentally I have not found any appreciable gain. The best results have generally been obtained with a current of 10 to 12 amperes, carbons 11 to 13 mm., and an arc length of 20 to 30 mm.

To obtain these long lengths with ease, it is necessary to use cored carbons or some other means of introducing foreign bodies, such as salts of potassium and sodium, into the arc, for there is not much doubt that the stability of the arc [fol. 2932] between ordinary cored carbons is due to the presence of potassium silicate in the core.[15] (See also Appendix I.) These salts may be introduced either by soaking the carbons in their solutions, or by using them as cores.

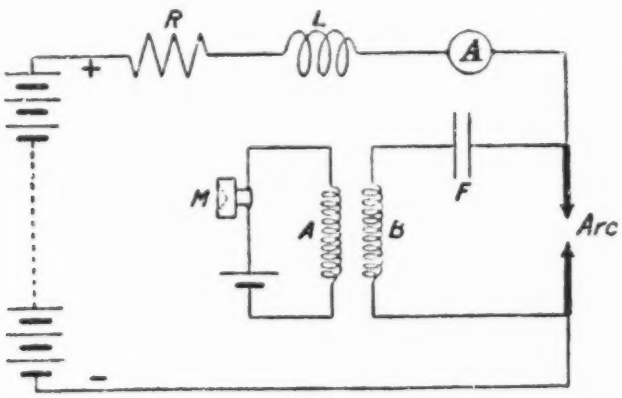

Fig. 3.

Mr. Jervis Smith has recommended the insulator glass as a core, which I find works well.

Arc as a Telephone Transmitter

Before leaving the subject of the use of the arc as a telephone, it will be convenient to consider its use as a telephone

[15] See Duddell and Marchant, *Proceedings of the Institution of electrical Engineers*, 1899, vol. xxviii., p. 66; Blondel, *International Congress of Electricity*, Paris 1900.

transmitter, though this subject strictly belongs to Part II. of this paper.

H. Simon found that if he replaced his microphone in Fig. 2 by a telephone receiver, *any sounds made near the arc were heard in the receiver*. In this case, as before, I find it preferable to modify his method by connecting the receiver in series with a condenser between the terminals of the arc, as in Fig. 4.

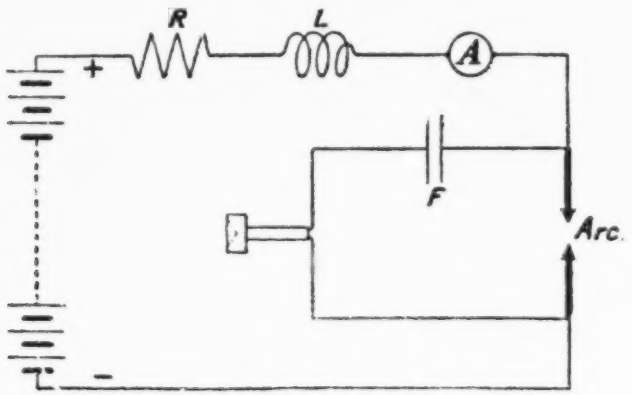

FIG. 4.

A sound-wave striking the arc may affect it in two ways, either by vibrating the arc as a whole and varying its length, [fol. 2933] or the waves of condensation and rarefaction may alter the cross-section of the arc: both of these effects will tend to alter the apparent resistance of the arc, and hence vary the current through it.

The sounds obtained in the telephone receiver when using the direct-current arc as a transmitter are not generally very satisfactory, as, besides not being very loud, they are obscured by the extraneous sounds due to the small spits and hisses which occur in the arc each time the air gets to the + crater due to any slight defect in the carbons. If a common pair of carbons be used containing cracks and impurities, the noise in the receiver is sometimes unbearable, although there is no outside source of disturbance of the current through the circuit.

In all experiments on the arc as a telephone transmitter or receiver, it is essential that the current generator should be free from rapid variations, or extraneous sounds will be produced. If a dynamo has to be used, then the variations of the current produced by the commutator segments may be minimised by inserting a large self-induction in

series with the arc, as in Figs. 1, 3, and 4. This self-induction serves the double purpose of keeping extraneous variations of the current out of the arc, and of preventing the variations we desire to observe from being dissipated in the source of supply.

Thus we see that *the direct-current arc is not only extremely sensitive to small variations in its current of almost any frequency, but also that it is affected by such small changes of outside conditions as sound-waves produce.* Whether this sensibility can be turned to useful account in telegraphy or telephony remains for future experiment to decide.

Part II

Current Caused to Vary by the Arc

Humming

Mr. Trotter [16] discovered that the direct-current humming arc rotates, including a coma-like appearance at the + crater, and he also found that the current through the arc varied periodically, the frequency of these variations being the same as the pitch of the humming sound produced, and as the speed of rotation of the arc.

In order further to investigate the connection between the variation of the light P.D. and the current, I have recorded the P.D. and current by means of an oscillograph, the humming arc experimented on being used as the source of light to illuminate the oscillograph mirrors. The arc was so inclined that only the light from the + crater and a small part of the vapour column reached the mirrors. So that the density at any point of the lines represents the photographic intensity of the light emitted at that instant in the direction of the mirrors by the + crater and part of the vapour column, and the distance of the point from this zero line measures the P.D. or the current as the case may be.[17]

---

[16] *The Electrician*, 1894, vol. xxxiii., p. 298.

[17] In Figs. 5, 6, and 7, the centre line is not the zero-line, but represents 20 amperes and 40 volts.

(Here follows 1 photolithograph, side folio 2934)

HUMMING ARC.

CARBONS: + 11 and − 9 mm. Solid "Apostle." Mean P.D. = 50·5 volts. Mean Current = 15·2 amperes.

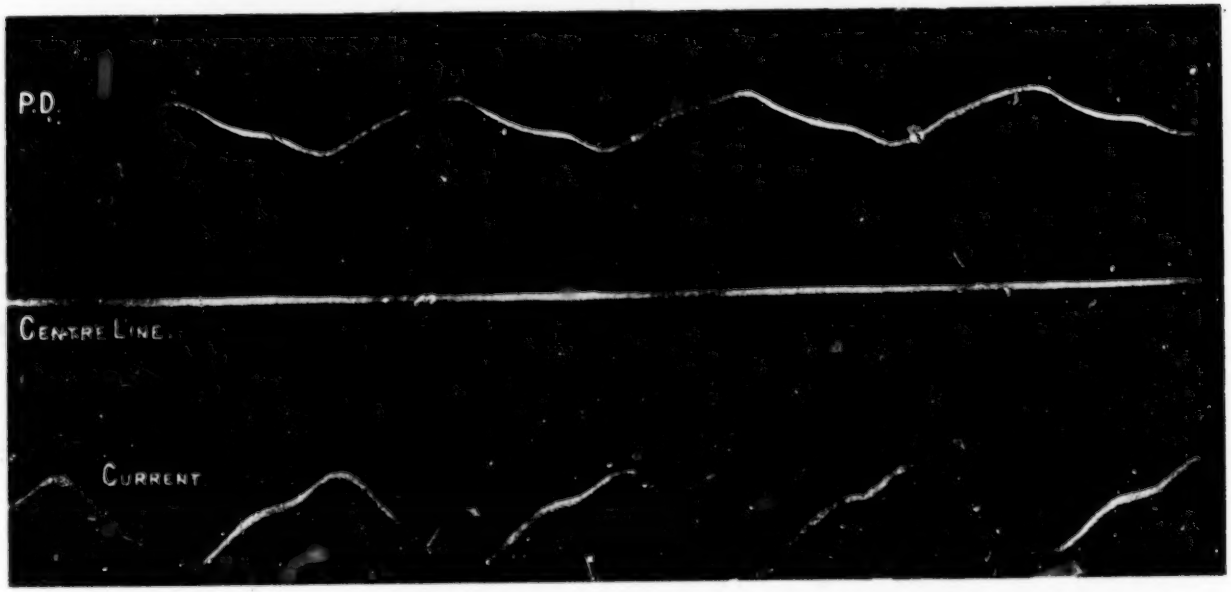

FIG. 5.

Scales.—1 mm. = 0·5 volt = 0.186 ampere = $\frac{1}{2400}$ second. Centre Line = 40 volts = 20 amperes.

2934

[fol. 2935] A typical example of the variations observed in the humming arc is given in Fig. 5, from which it will be seen that the P.D. current and light emitted in a fixed direction vary in a regular periodic manner with the same frequency.

The variation of the current, which is about 6 per cent. from the mean, is not sufficient to account for the large variation in the light emitted in the direction of the mirrors. This periodic variation of the light is most probably due to the fact that the arc rotates so that the + crater alternately either supplies light to the oscillograph mirrors, or is prevented from doing so by being on the other side of the + carbon. The periodic time of the variations of the light will, of course, be unaffected by a change in the position from which the arc is observed, but the times at which the light maxima occur relatively to the times at which the current is a maximum will depend on this position.

Thus besides the rotation of the humming arc and the variation of the current observed by Mr. Trotter, I find that the light and P.D. vary with the same frequency, so that in the humming arc the frequencies of the rotation of the arc, and of the variations in the P.D. current, and light emitted in a given direction, are identical with the pitch of the note given out.

. . . . . .

Musical Arc

A direct-current arc of suitable length and current, between solid carbons, will give out a musical note if it be shunted with a condenser in series with a self-induction, as

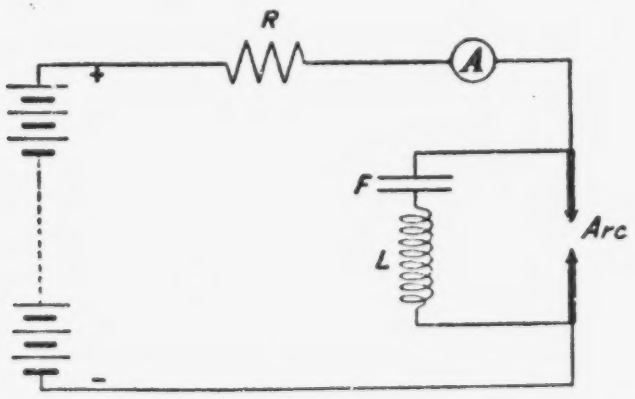

FIG. 9.

in Fig. 9, even though the source of supply of the current be perfectly constant and the arc be protected as far as possible from any outside cause of disturbance. [Experiment.]

[fol. 2936] I find that the musical note is produced by oscillatory currents flowing in the circuit composed of the condenser F, the self-induction L, and the arc, Fig. 9, and its pitch is determined by the periodic time of this circuit—that is, on the relation between the capacity, self-induction, and effective resistance of the circuit. Neglecting the resistance, which it will be shown later must be small, the periodic time of the circuit $\tau = 2\pi\sqrt{LF}$, and this has been found, by judging the pitch of the note by ear, to be approximately correct, so that for lecture purposes Kelvin's law can by this means be easily demonstrated. (See Appendix III.)

It must be remembered that although we have an alternate current through the condenser and self-induction, the source of supply is not an alternating one, and that *it is the arc itself which is acting as a converter and transforming a part of the direct current into alternating, the frequency of which can be varied between very wide limits by altering the self-induction and capacity.* The upper limit I find to be about 10,000 ~ per second, and the lower limit, if such exists, is well below 500 ~ per second.

It has long been known that a train of oscillations of almost any frequency can be obtained on discharging a condenser through a suitable inductive resistance, but of course these oscillations have a rapidly decreasing amplitude; and the means of supplying energy to such a circuit so as to maintain *the amplitude of the swings constant*, other than by means of a varying source of power having the same periodic time as the circuit, has been wanting. It is, therefore, necessary to inquire under what conditions it is possible for the arc to cause the source of direct current to supply the energy necessary to maintain the oscillations in the condenser circuit when once they have been started.

If the resistance in the main circuit in series with the arc is large, and if δV be a small instantaneous change in the P.D. between the terminals of the arc, δA the corresponding small change in the current through it, and r the resistance of the condenser circuit, not including the condenser; then, during the time this small change lasts, sufficient energy may be supplied to the condenser circuit to

make up for the energy dissipated there, in ohmic losses, if the following conditions are fulfilled (see Appendix II.):—

$$1.\ \frac{\delta V}{\delta A},\ \text{negative.}$$

$$2.\ \frac{\delta V}{\delta A},\ \text{numerically greater than } r.$$

The question is, can the arc fulfill these two conditions? Messrs. Frith and Rodgers[18] have experimentally deter-
[fol. 2937] mined the value of $\frac{\delta V}{\delta A}$, which they call the resist-
ance of the arc, for various arcs, and they found that while $\frac{\delta V}{\delta A}$ was always + when *both* carbons were cored, it was, on the contrary, always — when *both* carbons were solid; and that it was as small as −2 ohms for a 4-ampere solid arc. Now the resistance of the condenser circuit, r, external to the condenser, can easily be made less than 2 ohms, so that the arc can fulfill both the necessary conditions.

I will now describe some observations on the musical arc which tend to confirm the above conclusions.

Arcs between solid carbons for which $\frac{\delta V}{\delta A}$ is always negative *work well*, while those between *cored* carbons for which $\frac{\delta V}{\delta A}$ is positive I find *will not work* under any conditions.

[Experiment.]

The largest negative value of $\frac{\delta V}{\delta A}$ given by Messrs. Frith and Rodgers is 2 ohms for a 4-ampere solid arc, and it is probable that it did not exceed 2.5 ohms. for the smaller cur-

[18] *Proceedings of the Physical Society*, 1896, vol. xiv., p. 307.

rents, viz., 3 to 3.5 amperes, which I used. According to the above conditions, 2.5 ohms should be the limiting resistance of the condenser circuit; by experiment it was found that when the resistance of this circuit was increased to 2.4 ohms the oscillations stopped and could not be restarted. [Experiment.]

It is evident that besides the resistance there are other causes, such as hysteresis, which tend to dissipate the energy in the condenser circuit and stop the arc giving its note. The hysteresis in an iron-wire core introduced into the self-induction will instantly stop the note. [Experiment.] Any complete circuit such as a ring of wire placed near the self-induction has the same effect. [Experiment.]

On several occasions before the importance of these causes of the dissipation of the energy were realised, considerable trouble was experienced in tracing the reason of the arc failing to give its note. As examples, in one case it was traced to an ammeter and in another to the tinfoil in the condenser which were acting as short-circuited secondaries to the self-induction coil, which had been placed too near them. [Experiment.]

The relation between the self-induction, capacity, and frequency can be very easily demonstrated by playing a tune on the arc by varying either the capacity or the self-induction by means of a keyboard. [Experiment.] (See Appendix III.) [fol 2938] Another method of varying the self-induction is by separating or bringing closer together the turns of the coil, as if playing on a concertina, the relative positions of the turns determining the self-induction and the pitch of the note. The musical arc can be used as a means of comparing self-inductions or capacities by comparing the pitch of the notes produced.

The "enclosed arc" will work equally as well as the open arc, though the note given out is not so audible owing to the globe; but it can easily be made so by taking advantage of some of the telephoning effects mentioned in Part I.

The alternating current through the condenser circuit may be as large as from 3 to 5 amperes R.M.S. value, and the direct current in the main circuit also varies considerably depending on the amount of resistance in the circuit. This condenser current is sufficient to show experiments with alternating currents which do not require much power, and is very convenient in many cases for lecture purposes as the frequency, and any changes in it, are at once evident

from the pitch of the note given out by the arc. Magnetic space telegraphy can easily be demonstrated on a small scale by using the self-induction coil as the transmitting circuit. [Experiment.] Several arcs can be used in series when more power is required in the condenser circuit than can be obtained from one arc alone.

* * * * * * *

The President

The PRESIDENT: It is quite evident we have not time for much discussion, and I am sorry to say the discussion on this paper cannot be adjourned. I think, however, we ought to call upon Professor Ayrton to say how it bears upon that negative resistance of his which was so much maligned some time ago.

Professor Ayrton

Professor W. E. AYRTON: The paper which we have just heard read has given me exquisite pleasure: not because I have any claim to be its author, although I felt as pleased while I heard it read as if I had been the writer; nor is it merely because I feel convinced that these experiments of to-night will assist in the development of the electrical industry of to-morrow: it is rather because it so rejoices the hearts alike of professional men—yea, and of professors—to find a student who so resembles a solid carbon arc that he is ever on the alert to catch at and magnify any hint which may come from Nature or man. From Mr. Duddell's papers of two years ago, and of to-night, we learn much; among other things this second one has taught us [fol. 2939] how valuable was that research made some five years ago by Messrs. Frith and Rodgers. For what did that investigation really show us? It brought out an absolutely new fact. Supposing this is an alternating-current circuit (Fig. A), the alternator running at a given frequency and supplied with a given exciting current, the alternating current in the circuit being measured by an accurately graduated alternate-current ammeter, and that this is a wholly separate circuit—a direct-current circuit supplied by accumulators—and sending a direct current through a solid carbon arc. Then what they showed was this, that if you make a break in this alternate circuit and insert the solid carbon arc (Fig. B) without making any

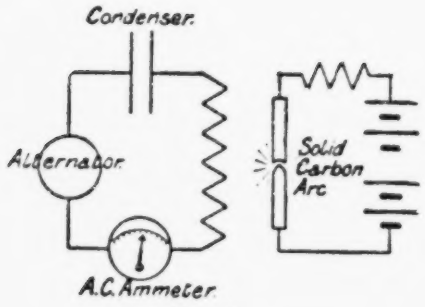

FIG. A.

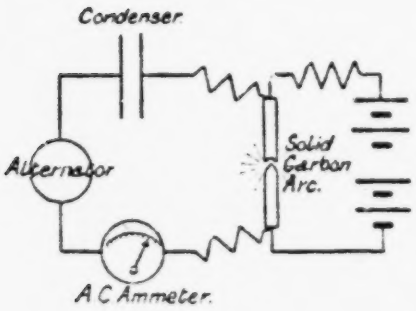

FIG. B.

change in the resistance, speed, or excitation of the alternator, etc., you increase the alternate current, not merely the current when flowing in one direction—for the condenser stops any direct current—but you increase the current in *both* directions; that is, the alternate-current ammeter reads higher after the arc has been inserted than it did before, and higher than it will if the arc be short-circuited. Now that investigation was undertaken by these gentlemen because certain theoretical considerations led me to suggest that if the method that had been employed by various experimenters to measure the resistance of the arc—a method employed without comment or adverse criticism as long as a positive answer was obtained—was applied in a certain case to an arc a negative answer for the resistance of the arc would be found: that the method, in fact, which up to that period had been used successfully to give the resistance of the arc, and which had always given a positive value, I pointed out would give under certain conditions, a negative answer. Certain preliminary experiments having been made by Mr. Mather which confirmed my idea, a long investigation was carried out by Messrs. Frith and Rodgers. And they found that whenever the arc was formed between *solid* carbons, the ratio of an instantaneous change of P.D. to the corresponding instantaneous change of current was *negative*, whereas if the carbons were *both cored* it was always *positive*.

[fol. 2946] A howl of indignant criticism followed. Had Messrs. Frith and Rodgers and I lived in the Middle Ages we should undoubtedly have been burned in the solid carbon arc. But there were three distinguished investigators

who had the insight, who had the courage, not to be drawn into this net of conventional antagonism, and these were Professor Gray, then of Bangor, now Lord Kelvin's successor at Glasgow, Mr. Oliver Heaviside, and last but by no means least, the Chairman of your Dublin local section, Professor Fitzgerald, to whom we, like so many experimenters, are indebted for the many suggestions which he has made. And I, even I, ventured to suggest that progress would be more expedited, I thought, if the critics, instead of merely cavilling at the anatomy of the sugar figure on the cake, would cut it open, and see whether there were really any plums inside. It has remained, however, for Mr. Duddell to be the real Jack Horner to put in his thumb and pull out the plum, and modestly leave you and me to finish the rhyme and add "what a good boy he is."

I do not propose this evening to consider whether or not what Messrs. Frith and Rodgers measured was the true resistance of the arc, because opportunity, I hope, we shall soon have of going fully into the subject; but in justice to Messrs. Frith and Rodgers, and in virtue of the far-reaching principle that they really brought to light, I desire to emphasise what they really obtained. Mr. Duddell has taught us what was the real significance of their work. Our lost friend Professor Hopkinson, following Mr. Wilde, proved several years ago that two alternators could not be run in series. Thus, for example, if an alternator with a certain exciting current supplied to it, and driven with a steam engine, or an electric motor, or whatever it might be, were coupled mechanically to another similar alternator, driven by an independent steam engine, and speed were got up so that the two machines were going exactly in step and then were joined in series with some outside circuit, he proved to us that the moment this mechanical coupling was severed the two alternators would get out of step. So, as is well known, two alternators cannot run in series. And he might have added—if there had been the slightest necessity for him to do so—that if two alternators cannot continue running in series even if they have been started with the same frequency and exactly in step, still more impossible must it be for one alternator, driven by its own steam engine, to run in series with another independently driven when the frequency of the second is being altered within

wide limits. Nevertheless, gentlemen, that is exactly what the arc does. For in Fig. B we have one alternator running in series, with a second alternator, viz., the solid carbon arc, supplying alternating current to the circuit—because the arc transforms direct-current energy into alternate-current energy—and does it in such a way that whether the frequency of this alternator be as Messrs. Frith and Rodgers found, seven periods per second, or 70, or 170, or 250, which was the highest limit which could be obtained in my laboratory at that time, and whatever the current [fol. 2941] might be within the limits they tried, this gallant little alternator—the solid carbon arc—helps the other, and supplies current sufficiently in phase as to make the alternate current greater when it, the arc, is inserted than when it is taken away or short-circuited.

Mr. Duddell has not only pointed out the importance of that result, the novelty of that result, but he has pointed out something even further. He has shown us that an ordinary so-called perfectly silent arc supplied with current from accumulators is, if the carbons be solid, like the mouthpiece of a flageolet or flute, not blown. The application of a shunt to that arc, consisting of a capacity in series with a self induction, performs two operations. It starts vibrations in the arc, just as blowing a flute gives rise to vibrations of many different rates. Just as one of those rates of vibration is picked out and reinforced in the case of a flute or flageolet by the form of the resonance chamber dependent on the position of your fingers or keys, so in this musical arc the particular one of the many vibrations that is probably started which is picked out and reinforced depends on the capacity of the condenser and the value of the self-induction which is in series with it.

Already he has shown you a practical result that has followed from this. I do not mean merely those illustrations which he has given of magnetic space telegraphy, and by means of which he has shown how it has become possible to easily and experimentally demonstrate that the E. M. F. of the current induced in the distant secondary coil is proportional to the frequency of the alternating current in the primary, which will be of marked value to teachers; but beyond that he has shown us how to much improve a well-known instrument. The other day he demonstrated in my laboratory that, adding to the ordinary circuit of that very

induction-coil, joined up as usual, his little motor so as to put the condenser across the break *just after* the break was made, a spark was obtained from five to seven times as long as was obtained with the coil in the ordinary way. Even if you try to make the comparison absolutely fair, and try to arrange the very best conditions in each case for the old method and for the new method, you still find a great advantage. Let somebody take, for example, an induction coil and arrange the battery-circuit, contact-breaker, etc., in the old way as well as he can, and let Mr. Duddell use the same induction-coil, battery, condenser, etc., and deal with it as well as he can, then the spark produced in the latter case will be from $2\frac{1}{2}$ to 3 times as long as in the former.

There is one other point which has come out in connection with these experiments of a rather different kind. Some ten or more years ago a paper was read by Dr. Sumpner and myself before the Royal Society, pointing out what was then new, that in the case of an alternating-current arc, if we used solid carbons, the true power given to the arc, that is the power measured by some accurate method, was considerably less in some cases than the current meas- [fols. 2942-2943] ured by a good current ammeter multiplied by the pressure measured by an alternate-current voltmeter. Subsequently to that, in making experiments I was pretty convinced that under certain circumstances a direct-current arc behaved in the same way. I was pretty certain, in the case of a direct-current arc, especially when solid carbons were used and the arc was hissing, that the power-factor was no longer unity, but not sufficiently sure of the fact to publish it, especially in view of the way in which that other paper which I have just referred to was received at the Royal Society, and the scepticism which was raised when Dr. Sumpner and I pointed out how far from unity we found the power-factor was with certain alternate-current arcs. But now I am sure, from results of experiments which have been recently made in my laboratory, that with an arc supplied with accumulators, a so-called steady direct-current arc, if the carbons be solid and there is hissing, the power-factor may be several per cent. different from unity—that is, the true power as measured by a true instrument, for example a good wattmeter, may be several per cent. less than the product of the voltmeter reading into the ammeter reading.

When I read this paper of Mr. Duddell's, I thought he had proved that a solid carbon direct-current arc was the most sympathetic soul I had ever met, but you have convinced us that that is not quite the case for you have shown Mr. Duddell this evening that the sympathy of his arc is even exceeded by the sympathy of his audience.

[fol. 2944] DEFENDANT'S EXHIBIT Z

United States of America,
Navy Department,
Washington, July 7, 1923.

I hereby certify that the annexed Blueprint copy of "Bellini-Tosi Direction Finder Tests", prepared by Mr. George H. Clark, while on duty at the Radio Test Shop, Navy Yard, Washington, D. C., in the year 1915, is a correct copy of the original now on file in the Radio Test Shop, Navy Yard, Washington, D. C.

F. H. Brumby, *Captain, U. S. Navy, Acting Commandant.*

Office of the Secretary.

I hereby certify that F. H. Brumby, Captain, U. S. Navy, who signed the foregoing certificate, was at the time of signing Acting Commandant, Navy Yard, Washington, D. C., and that full faith and credit should be given his certification as such.

In testimony whereof, I have hereunto set my hand and caused the Seal of the Navy Department to be affixed this fifteenth day of July, one thousand nine hundred and twenty-three.

(Seal.) T. Roosevelt, *Secretary of the Navy.*

[fol. 2945] 1. *Description of Apparatus.* — The apparatus consists essentially of the following parts:

a. Two special antennas.
b. One direction-finder system.
c. One receiver with detector and accessories.
d. One angle-bisector.
e. One tester.

(a) The antenna system consists of two triangular, insulated, ungrounded antennas of equal size, the plane of one being exactly at right angles to the plane of the other. RW69A96A shows a typical aerial on land, and RW69A94A shows the method of installation on shipboard. Since by far the greatest use of the device is on shipboard, the names assigned to the aerials correspond to the location of the aerial with reference to the ship. One aerial is called the "Port forward-starboard aft" aerial, the other the "Port aft-starboard forward" aerial. Similarly, the horizontal leads from the lower ends of the sloping antenna wires to the receiving apparatus are known by the quarter of the ship in which they lie, as "Port forward", "starboard aft", etc. As shown in the drawing, the planes of the aerials lie at an angle of forty-five degrees with the fore and aft plane of the ship; this is done in order to obtain as great a length of base line as possible. Other things being equal, the dis-

tance-efficiency of the direction-finder increases with increase in base line.

When installed on shipboard, the triangular aerials are usually suspended by their top corners thru insulators from a triatic or other fore and aft stay, or from a sprit, gaff, or bracket on one of the masts. Connecting wires are led to the instruments from the centres of the horizontal base lines of the triangular aerials, which are split by an insulator at their point of intersection. The range of the installation suffers to some extent if these connecting wires are very long, so that it is desirable to keep the distance between the instruments and the centre of the aerial system as short as practicable.

(b) The direction finder system consists of two coils of wire of equal size, crossing each other at right angles in vertical planes. In the middle of each coil of wire is inserted a variable condenser of the sliding plate type; this location being for reasons of symmetry. Inside the crossed coils a third coil, called the "exploring coil" is mounted on a vertical spindle, so that its angular position with reference to the fixed coils can be varied. On this spindle is mounted the indicating handle from which the direction is finally read. RW69P92 shows the exterior of the Direction-Finder, and RW69P95 the interior. The connections of the primary coil system are shown in print RW69A92A; the dimensions and value of the primary coil system in RW69A83A; the mechanical details of the sliding plate condenser in RW69A82A; and the calibration of this latter in RW69A81A.

Each aerial passes thru a double pole switch, which, when opened, completely disconnects the aerial from its associated coil system. Safety spark gaps serve to take care of any high potential developed in the aerial due to the local transmitter or other causes.

[fol. 2946] The inductance of one side of one of the primary coils is 0.0046 m. h., and the total inductance of the two halves of one coil is 0.018 m. h.

The series primary condenser has a maximum value of 0.0014 mfd. The fixed plates are provided with an adjusting screw, so that the absolute value of capacity at any given setting may be varied within certain limits. The series condensers of both aerials are varied simultaneously, hence if there should be a slight dissimilarity in the constants of

the two aerials both would not be exactly in resonance if both condensers had exactly the same value. Hence by the adjusting screw any difference in antenna constants can be offset once for all by a variation in the value of the series condenser associated with the antenna, the other series condenser remaining unchanged.

The pick-up coil which rotates inside the primary cage is shown as coil L'_2 in RW69A77A. Its inductance is 0.155 m. h. at 1,000 meters.

(c) The receiver system is shown in photos RW69P93, 94, 96, 97, and 98. The wiring is shown in print RW69A92A.

The intermediate circuit which acts to transfer energy from the primary squirrel-cage coil system to the detector system consists of two coils and a variable condenser, all three being in parallel with each other. The variable condenser is of the Marconi ebonite-plate type, and has a maximum capacity of 0.011 mfd. This is very much greater than is required to reach the wave lengths intended when used with the associated coil system. An air-dielectric variable condenser would be far preferable. The calibration of this Marconi condenser is shown in RW69A78A. The constants of the intermediate circuit inductances and of the detector circuit inductance and the coupling between these circuits is shown in RW69A77A. This coupling is variable by a handle projecting from the receiver box, and marked "Intensifier handle". The choice of term is not ideal.

The detector circuit consists of a cylindrical inductance of value 0.60 m. h. at 1,000 meters, and a sliding tubular condenser, this latter being known as a "billi" condenser. The term is given on account of the mythological value of capacity supposed to be available with this condenser, i. e., one billionth of a farad. As a matter of measurement, the condenser varies from 0.000016 mfd. to 0.00024 mfd. The construction of the condenser is shown in RW69A80A, and the calibration in RW69A79A. This condenser is also known as the "jigger" condenser.

Two detectors were supplied with the set, (1), carborundum, and (2), Fleming valve.

The general diagram and also RW50A106A show the diagram of connections for the valve. A series resistance Rh, varies the filament current and hence the brilliancy of the filament. A potentiometer RH, varies the potential

on the enveloping plate. These resistances are in series with each other, hence a variation in the series resistance (to vary the filament brilliancy) requires a readjustment of the potentiometer. A six-volt storage battery is used for current supply. This battery with its associated charg- [fol. 2947] ing and connecting plug, and also voltmeter, is shown in RW69P98.

When using the crystal detector, the potentiometer alone is in use. The series resistance is in circuit, but is no longer a factor in adjustment.

A simple two-way switch serves to connect valve or crystal.

(d) In obtaining the direction of a sending station, as explained in the next paragraph, greater accuracy is obtained by noting the position on each side of the maximum at which signals die off to a certain equal value. The direction-indication is then the mean of these two angles on either side of the maximum. For rapid determination of this mean angle an angle-bisector is supplied with the apparatus. See photo RW69P100. If the two outer arms be set at angles corresponding to the reading of the direction finder each side of the maximum position, the middle arm automatically indicates the mean of these two angles.

. . . . . .

2. *Operation of Direction Finder.*—Each aerial loop forms a directional aerial, which receives best when its plane is in the direction of the sending station. If the plane of the aerial is at right angles to the direction of the sending station, equal and opposite currents are set up in each side of the loop, and the net result is zero. When the plane is in the direction of the sending station, currents of different phase are set up in the two sides of the loop, the phase difference depending on the relation between the wave length and the length of the base line of the aerial. Hence a resultant current flows thru the system. When the plane of the aerial is intermediate between the positions described above, the induced current varies as the cosine of the angle between the plane of the aerial loop and the direction of the sending station.

. . . . . .

3. *Experiments With the Direction Finder.*—Tests made between May and September, 1914.

f. *Sending station.*

After the first few tests on the Direction Finder, the galena detector was used for all tests.

s. Tests of direction:

. . . . . .

t. Sensitiveness of direction finder apparatus as a whole.

. . . . . .

u. Reactance curves of aerial systems.

. . . . . .

v. Recommendations:

1. Replace secondary condenser (Marconi type, with ebonite dielectric) by standard air condenser. Present condenser is much too large for the wave lengths normally used with the apparatus, is liable to get out of order, and has serious internal losses.

2. Replace carborundum detector and Fleming valve by more sensitive crystal detector (as galena or silicon-arsenic) and Deforest audion amplifier. Possibly it would be sufficient to supply binding posts for this, and use the detectors available at the station of use.

[fol. 2949] 3. Tests should be begun to devise a method of direction finding which, as this one, is independent of the movement of the ship, (i. e. does not require orientation of the ship to determine direction), but which has a much greater range. The limited range of the Bellini-Tosi ap-

paratus, even on land where an antenna of considerable size can be erected, is a severe disadvantage to the system.

Approved.

DEFENDANT'S EXHIBIT A-1

Manual of Wireless Telegraphy (Radio)

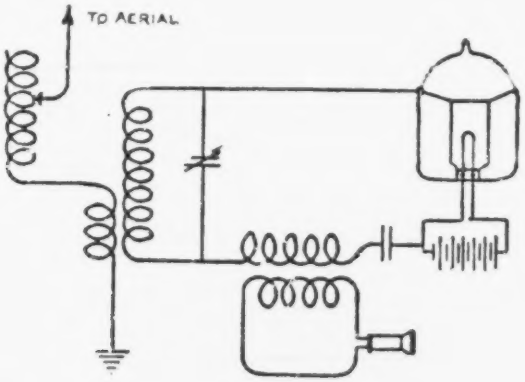
For the use of Naval Electricians by Commander S. S. Robison, U. S. Navy, 3d Revised Edition. Annapolis, Md., the United States Naval Institute, 1915

U. S. Naval Wireless Telegraph Station, Sitka, Alaska.

199. The variable inductance of fig. 83 is hinged so that the coupling can be varied by a combined movement of

separation and rotation with reference to the fixed inductance (fig. 100).

[fol. 2952] In fig. 86 the coupling is varied by sliding the closed circuit inductance on a graduated bar parallel to its axis (fig. 101a).



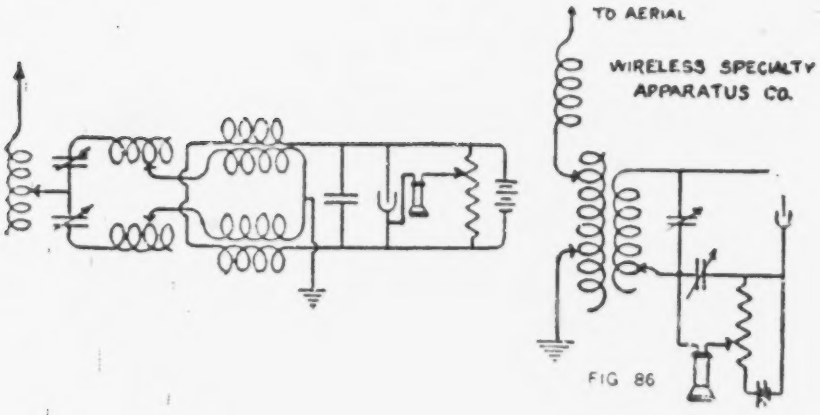


FIG 86

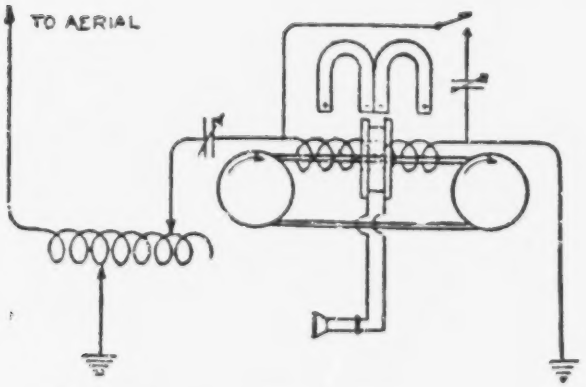

FIG. 87.—Magnetic Detector—Marconi.

Figs. 84 and 88 represent the valve and audion receiving circuits. In fig. 84, the valve detector is shown as shunted [fol. 2953] around a tuned, closed circuit. The audion shown in fig. 88 has tuned connections like the valve detector, but has a local battery in the telephone circuit.

Fig. 92 represents circuits of a receiving set complying with present specifications. In all such sets closed circuits are calibrated and curves drawn or a scale furnished show-

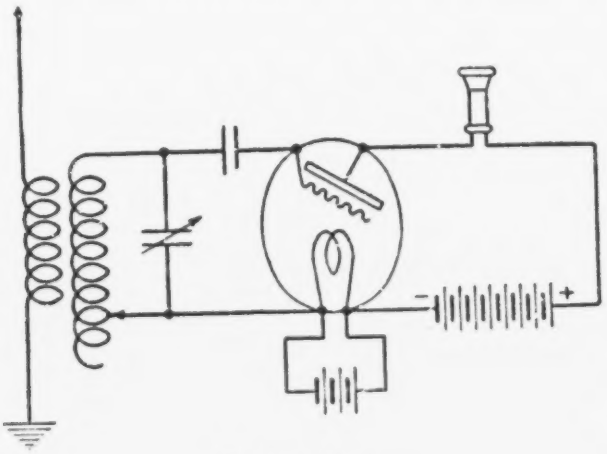

Fig. 88.—Audion.

ing wave lengths for all settings from 200 to 4000 meters, and additional calibrated loading coils for very long waves are supplied.

With very loose coupling the wave length of received signals can thus be read directly.

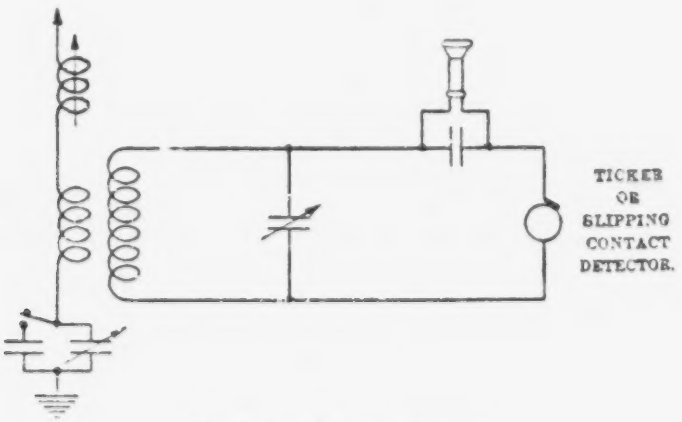

Fig. 89.—Federal Co. (Poulsen).

200. Fig. 89 represents receiving circuits for continuous oscillations; it shows the receiving telephone connected across the terminals of a fixed condenser in series with the detector.

In using undamped oscillations for wireless telegraphic purposes it must be remembered that the frequency of the oscillations themselves is too high to be heard in the telephone connected with the ordinary receiving circuit, and when the circuit at the sending station is closed all that would be heard is a slight click, so that there is no way of [Feb. 2954] telling a

. . . . . .

being wound in a spiral groove on an ebonite cylinder. A sliding contact, on a rod parallel to the cylinder, works in the groove and is pressed against the wire by a spring. By revolving the cylinder an infinite number of adjustments can be obtained.

Earlier Fessenden sets (figs. 79 and 82), have double roller inductances, by turning which, the wire can be reeled from one roller to another as desired. On one roller the turns are insulated from each other and on the other they are short circuited so that any desired length can be retained in the circuit.

None of the above types of variable inductances can be readily mounted so as to vary the mutual induction between them by any definite amount. They are suitable for loading but not suitable for loose coupling.

For this reason the preferred types of receiving circuits are made up of fixed inductances (or those varied by plug or dial stops), mounted so that they can either be coiled apart or one coil revolved so as to change its plane and hence the mutual induction with reference to the other or others. The variometer type, mounted like variable condensers, are now being manufactured. Their self induction can be varied quickly and conveniently and close adjustment of period (tuning) made with them or with the variable condensers, but the entire coil is always in circuit.

Each section of an inductance not in circuit should be opened at both ends, i.e., entirely disconnected, and if its natural period is large it should be mounted so that the inductive effect of active parts on it is a minimum. This applies especially to loading coils for long wave lengths. (Fig. 92.)

All inductances are wound on hard rubber, porcelain or glass and so as to have a minimum high frequency resistance. The decrement of the entire circuit must not exceed .3.

From the formula for damping $d=\frac{R}{2nL}$ it can readily be seen that a very pronounced natural period—a stiff circuit—can not be obtained unless the self-induction is large compared with the total resistance (including the radiation resistance.)

205. *Detectors.*—There is but one type of detector now in general use, viz., the *Crystal* or rectifying detector. The *electrolytic* is used only as a standard for comparison. Coherers and microphones are practically obsolete, and comparatively few of the magnetic and audion, or valve detectors, have been installed, but the use of audions and ultra-audions is increasing. Unlike coherer detectors, all types of crystal, magnetic, electrolytic and audion detectors are self-restoring. Generally speaking all should be put on open circuit while sending, to preserve them from injury due to induced potentials and currents.

The ordinary detector serves as well for receiving the continuous modified oscillations of *wireless telephony* as for the groups of oscillations in ordinary wireless *telegraphy*.

[fol. 2955] 206. *The electrolytic detector.*—It consists of a fine platinum wire just touching an electrolyte made either of a 20% solution of nitric or sulphuric acid or an alkali. Of these the nitric acid solution is preferred. The other electrode is also of platinum. The containing cup (fig. 79) is made quite small so that the cohesive power of the electrolyte will prevent splashing in a sea way. The electrolytic detector must have the fine wire terminal connected to the positive pole of the local battery (fig. 79), otherwise the device is not operative.

Dr. Austin states that the higher the frequency, the finer the wire should be, and that the depth of immersion does not matter if the detector is not directly in series in the closed circuit.

When a current flows through the electrolyte, the latter is decomposed (the action being called electrolysis) liberating oxygen at the anode and hydrogen at the cathode. The accumulation of these non-conducting gases on the electrodes

interferes with the passage of the current, which soon ceases to flow and the cell is then said to be *polarized*.

The fine wire anode is then insulated by the oxygen, which forms the dielectric of a small condenser, of which one conducting surface is the electrolyte and the other the wire point.

The critical potential of the detector is just below that necessary to break down this insulating layer of oxygen and is determined by increasing the potential at the detector terminals by means of the potentiometer until a bubbling or hissing sound is heard in the receiving telephone; then resistance is cut in until this sound just ceases.

When electric oscillations are impressed on this condenser, the polarization layer breaks down and permits a pulse of direct current from the battery to pass through the cell and *telephone*. As soon as the oscillations cease the polarization is restored.

Except when they are very strong, the loudness of the sounds produced in the telephone is an exact measure of the energy of the oscillations passing through the cell.

This constancy of action of the electrolytic cell is utilized as a means of comparing the sensitiveness of detectors, the standard being the sensitiveness of an unjacketed platinum wire electrode .0002 in diameter in a solution of 20% nitric acid.[1]

Glass jacketed electrodes formed by sealing the wire in glass (the two having the same coefficient of heat expansion) have been used, but are less reliable and in general less sensitive and are no longer supplied. Some of these glass points were made hook shaped, the hook pointing upward to facilitate depolarizing but no increase in sensitiveness was noted on this account.

With the Shoemaker receiving sets was furnished what was called a primary cell detector. The electrolyte used was a 20% solution of sulphuric acid and the other electrode was a zinc rod amalgamated with *mercury*, which in the acid solution gave a difference of about .7 volt between zinc [fol. 2956] and platinum. No local battery was required (fig. 82). At times this detector compared favorably with

[1] Dr. Austin has invented a "detector tester" which affords a means of direct comparison between detectors operating under the same conditions.

the one just described, but was in general more irregular and less sensitive in its action.

In all electrolytic detectors very strong signals or static discharges produce actual sparking or an explosive action in the electrolyte, which destroys the platinum point and an operator must be constantly on the lookout to protect his point from burning out. The best results in electrolytic detectors have been obtained with a distance between electrodes of approximately $\frac{1}{4}$ inch.

207. *Rectifying detectors.*—There are certain substances which when brought together in not too close contact, have the property of producing a direct current when an alternating current or electrical oscillations are sent through them. The cause of this action is not yet known. Among these substances are carbon in contact with steel, tellurium with aluminum or galena, silicon with any of the ordinary metals, and certain crystals.

The first of the crystal detectors to be supplied was General Dunwoody's carborundum crystal detector.

Since rectifying detectors permit the passage of current in but one direction, they produce pulses of direct current. These pulses, if strong enough, can be heard in a telephone so that local batteries are not required, although a slight increase of sensitiveness is noted in some detectors with an E.M.F. across the terminals of the detector of about 0.2 volt.

Rectifying detectors are connected in receiving circuits in the same manner as the electrolytic.

Their sensitiveness for general use is practically equal to the electrolytic and their simplicity makes them the more suitable. They are in general less sensitive to injury from static discharges, strong signals, or induced currents from sending, than the electrolytic, but, like coherers, different crystals of the same material vary widely in sensitiveness and sensitive spots in any crystal have to be found by trial and when found are not constant. They are thus not as capable of quick readjustment as the electrolytic, but their other advantages are such as to be conclusive as regards their use.

The carborundum detector when first introduced, was simply held between two points or wrapped with copper wire for one connection, with a needle, knife edge, or more blunt piece of metal for the other. It was later found that embedding a large part of the crystal in a conductor such

as solder or a mercury paste, and thus limiting the rectification to one contact only, produced much better results and carborundum crystals have been found equal in sensitiveness to other crystals now generally utilized.

Pickard's silicon detector followed the carborundum and is still in use but it has been largely superseded by the Perikon & Pyron, supplied with the receiving set illustrated in fig. 86. The Perikon detector consists of two crystals, chalcopyrites and zincite. A number of zincite crystals are held in a conducting disc, a crystal of chalcopyrites is mounted [fol. 2957] so that it can be brought into contact with any part of any of the zincite crystals at will, and the pressure between the two *regulated*. In the adjustment for maximum intensity of signals, the exact degree of pressure and the most favorable points of contact are of importance. These can only be ascertained by trial and test with the testing buzzer.

The sensitiveness of the Perikon may be approximately doubled by connecting a battery across its terminals so as to give approximately 0.2 volt. The positive pole must be connected to the single crystal.

The Pyron consists of a crystal of iron pyrites in contact with a metal point like the silicon. This is very satisfactory for strong signals and constant in its action. The iron pyrites is more sensitive when the pressure of the metal point is adjustable. The *area* of contact is also a determining factor of sensitiveness; comparatively fine points will discover sensitive places on irregular crystals, which blunt points will not.

The Perikon is more sensitive and must be protected against strong signals. The *zincite* is the crystal injured by strong signals. It should not be subjected to heavy pressures or grinding from the chalcopyrite. When deadened the zincite crystals can be made operative by scrubbing them with a bristle brush wet with carbon bisulphide, then with soap and water and then rinsing with fresh water and drying. In damp weather or in tropical climates this detector is improved by spreading a drop of paraffin oil over the surface of the crystals. This comment applies to the silicon also.

Galena, cerusite (a form of galena), and iron pyrites are all giving satisfactory use by mounting so as to have contact all over one surface and a very fine, flexible wire point just touching *the other* surface.

208. *Vacuum tube detectors.*—The two forms which have been used are known as the valve and the audion, illustrated in figs. 84 and 88. The valve was discovered by Fleming, and is sometimes called the Fleming valve. It is a rectifier, permitting the passage of current in one direction only. It consists of a special incandescent lamp (see fig. 84), operated by a 12-volt storage battery and having a small sheet or cylinder of metal held in the bulb near the filament. Lamp filaments when glowing emit negative electricity, which carries away part of the filament and causes the darkening of the bulb seen on old carbon lamps. The vacuum thus becomes a conductor in one direction only. It is not found to be a very sensitive one.

The audion (fig. 88) has a metal grid interposed between the metal plate and the lamp filament. In the valve, the metal plate is connected to the receiving circuit, but in the audion, the grid is connected to the receiving circuit, while the plate is connected to the telephone. In the valve, the variations of current in the receiving circuit produce differences of potential between the filament and the plate. In the audion, these differences of potential are between the filament and the grid: or, as it is perhaps better to say, the grid is charged by the received oscillating currents. In [fol. 2958] addition to this difference, the audion has a local battery with its positive pole connected to the metal plate, and its negative pole to the lamp filament. This battery, as well as the battery supplying the lamp, has a variable voltage. The battery voltage and lamp voltage must both be adjusted to secure the greatest sensitiveness of this detector; but this adjustment is permanent for any given conditions. The charge on the grid, produced by the incoming signals, interferes with the flow of negative electricity between the filament and the plate. This flow of negative electricity, when the heat from the filament and the local

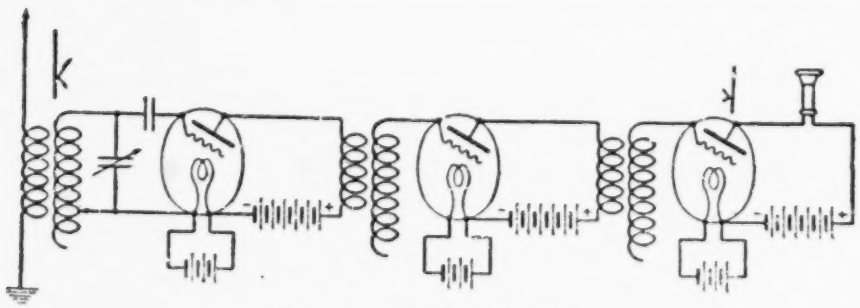

FIG. 88A.—Amplifying Audion.

battery voltage are properly adjusted, produces a current through the audion of the order of a milliampere. This current flows through the receiving telephone and variations in it, produced by the varying charge on the grid, are what make the signals heard in the telephone.

The audion has the further advantage over the valve, in that the telephone can be replaced by the primary of a transformer, the secondary of which is connected to another audion, with the result of amplifying the signals produced. (See fig. 88a.) Audion bulbs have tantalum lamp filaments, and plate and grid are usually double, one on each side of the filament. The plate and grid are of nickel. The audion can also be used as a heterodyne (art. 201). When connected for receiving continuous oscillations it is called "the ultra-audion."

We see, therefore, that the audion is suitable for use with arc, as well as spark sets, and also as an amplifier: thus combining within itself the qualities of all other detectors.

209. *Magnetic detectors.*— The operation of magnetic detectors depends on the fact that when iron is being magnetized its magnetization is somewhat delayed in time behind the impressed magnetizing force, and when in this condition the iron is very sensitive to any change in the magnetizing force, a very small increase of which will produce a momentarily large increase in the strength of the magnetic field.

Many patents have been issued for various forms of magnetic detectors, the best known and the most largely used of which is Marconi's, patented in England in 1902. It is not [fol. 2959] injured by strong sending, but is not as efficient as the crystal detector, the electrolytic nor the audion.

In its present form it consists of a flexible band of silk-covered iron wires, moved by clockwork around two pulleys which support it. A glass tube, through which the band passes, has a primary winding of insulated wire in series with the aerial and a secondary winding forming a closed circuit through a telephone. Close to the secondary windings are placed similar poles of two horse-shoe magnets, which magnetize the iron band slowly moving under them. Electric oscillations in the primary winding, produced by passing electric waves, produce momentary changes in the magnetization of the iron band under the magnets, and

these changes induce oscillating currents in the secondary winding which produce sounds in the telephone.

An elementary diagram of this magnetic detector is shown in fig. 87. It requires no local battery, and, not being subject to burnouts except from very large currents, it is a very convenient instrument, but is not as sensitive as those previously described, especially for short wave lengths. There are other methods of connecting this detector than that shown in fig. 87, but since comparatively few magnetic detectors are in use they are not shown here.

Defendant's Exhibit B 1

Robinson's Manual of Radio Telegraphy and Telephony, 1918

205. *Detectors.*—There are two types of detectors now in general use, viz., the *Audion*, and the *Crystal* or rectifying detector. The *electrolytic* is used only as a standard for comparison. Coherers and microphones are practically obsolete, and comparatively few of the magnetic detectors have been installed, but the use of audions and ultra audions is increasing. Unlike coherer detectors, all types of crystal, magnetic, electrolytic and audion detectors are self-restoring. Generally speaking all should be put on open circuit while sending, to preserve them from injury due to induced potentials and currents.

The ordinary detector serves as well for receiving the continuous modified oscillations of *wireless telephony* as for the groups of oscillations in ordinary wireless *telegraphy*.

206. *The Electrolytic Detector.*—it consists of a fine platinum wire just touching an electrolyte made either of a 20% solution of nitric or sulphuric acid or an alkali. Of these the nitric acid solution is preferred. The other electrode is also of platinum. The containing cup (fig. 79) is made quite small so that the cohesive power of the electrolyte will prevent splashing in a sea way. The electrolytic detector must have the fine wire terminal connected to the positive pole of the local battery (fig. 79), otherwise the device is not operative.

[fol. 2960] DEFENDANT'S EXHIBIT C 1

Wireless Telegraphy and Telephony

An Outline for Electrical Engineers and Others by

L. B. Turner, M.A., M.I.E.E., Fellow of King's College, Cambridge; recently of the Signals Experimental Establishment, Woolwich (Royal Engineers), and of the Engineer-in-Chief's Office, Post Office; Member of the Imperial Wireless Telegraphy committee 1919-20. Cambridge, at the University Press, 1921

example, the triode[1] produced by H. J. Round of the Marconi Company, shown at C in Plate XVII, would generally give wonderful results in expert hands; but it had to be carefully nursed, and its vacuum was actually controlled by the operator from time to time by warming more or less the pellet of asbestos sealed in a pocket in the tube, and visible in the photograph. In other tubes, a mercury amalgam was introduced for a similar purpose.

6. *Introduction of third electrode.*—We pass now to the effect on the space charge of introducing into it, or near it, a third electrode, maintained at a higher potential so as more or less to neutralise the charge. The tube then becomes a three-electrode tube, and is called a "triode." The third electrode is usually in the form of a perforated plate, or a wire grid, placed between cathode and anode, and is commonly called the "grid."[2] The introduction of the grid was the work of L. de Forest in 1907, and although the rationale of the triode does not appear to have been fully understood at the time, and its uses have only recently been developed, this addition to the Fleming Valve marks the conversion of the thermionic tube from a mild convenience into the potent and indispensable instrument it is to-day.

The reader will be helped to some physical picture of the action of the grid by studying the diagrams in Fig. 58. Here

[1] The fact that this is a triode and not a diode is irrelevant in this connection.

[2] "Control electrode" (grid) and "repeat electrode" (anode) are good descriptive terms, used by Eccles. Most commonly, the electrodes are referred to as filament (or cathode), grid, and anode (or plate).

C, G and A are sections of the cathode, grid and anode, which may be regarded for simplicity as portions of large plane surfaces perpendicular to the paper. The diagrams are intended to show the lines of electric force in the space between anode and cathode which would act upon the electrons if any were present, urging them to move in the direction against the arrow-head (since the electron is a *negative* charge). The presence of the electrons modifies the field in a manner not easy to portray, but by first considering the field in their absence we can obtain some insight into the action of the grid. To arrive at the electron currents, which are stated on the right of the diagrams, we have to picture a cloud of electrons congregated near the cathode, repelling freshly evaporated electrons.

Guide to the Study of the Ionic Valve

Showing its Development and Application to Wireless Telegraphy and Telephony, by William D. Owen, Associate Member of the Institute of Electrical Engineers, Head of the Department of Wireless Telegraphy, Rutherford College, Newcastle, 1919

IV. *The "Audion" or Three-Electrode Valve.*—The two electrode valve is now obsolete except in a modified form called the "Kenotron," to which reference is made later on. It was abandoned in favour of carborundum, which is more sensitive and requires less auxiliary apparatus. By the introduction of a third electrode into the valve between filament and plate, Dr. Lee de Forest, of New York, made use of an entirely new principle. The additional electrode must be such as to have capacity with respect to the filament and, in spite of its position, must allow electrons to pass to the plate. Incidentally it might be mentioned that the capacity effect between the *plate* and the third electrode is made use of in some circuits.

DEFENDANT'S EXHIBIT E-1

Proceedings of Physical Society of London, 1914

This shows the "Perikon" or zincite-chalcopyrite detector to be the most sensitive of those tested when used as a simple rectifier. The table also gives the maximum meas-

ured values of the sensitiveness for the various detectors tested when used with boosting voltage.

Table showing the relative sensitiveness of various detectors

Detector	Maximum sensitiveness when used as simple rectifiers	Maximum measured sensitiveness with boosting voltage
Marconi magnetic, assumed as unity		
Molybdenite-copper point	2 15	2 15
Graphite-steel point	1 26	
Carborundum, one end set in solder	0 50	0 60
Carborundum, not set in solder	0 325	1 0
Galena-plumbago	8 35	[1]12 6
Zincite-copper point	6 6	
Zincite-brass point	3 43	
Chalcopyrite-copper point	0	
Chalcopyrite-brass point	0	
"Perikon" (zincite-chalcopyrite)	10 5	12 1
Bornite-copper point	1 0	
Bornite-carbon point	0	
Zincite-bornite	7 4	7 4
Fleming carbon-filament valve (No. 12)		1 0
Fleming 12-volt metal-filament valve		1 0
Fleming 15½-volt metal-filament valve (No. 33)		12 0
Tellurium-aluminum	..	0 9
Electrolytic (German make)		1 0
Electrolytic-nitric acid		4 0

[1] NOTE.—It the *general shape* of the sensitiveness curve for the galena detector may be assumed to remain the same for very light contact as for firmer contact (with which the above measurements were taken), the maximum *estimated* sensitiveness for this detector with very light contact is *of the order of 60 to 70*, as compared with the magnetic detector.

[fol. 2962] Since the exact values of the current, voltage, &c., obtained in these tests for the various detectors will necessarily differ with different crystals, tables giving the results of the measurements are not given, but sample curves are included to show the general form of these results, as the *general shapes* of the curves will probably remain the same for the same substances.

DEFENDANT'S EXHIBIT F-1

Department of Commerce and Labor. Bulletin of the Bureau of Standards, Vol. 6, No. 4, S. W. Stratton, Director. Issued November, 1910. The Comparative Sensitiveness of Some Common Detectors of Electric Oscillations. Louis W. Austin, 527. Washington, Government Printing Office, 1910.

The Comparative Sensitiveness of Some Common Detectors of Electric Oscillations

By Louis W. Austin

Although probably many comparisons of the sensitiveness of detectors have been made in the laboratories of the wireless companies, very little quantitative information on this subject has been made public. For this reason the experiments here described have been carried out. On account of the difficulties and the amount of time involved in the testing of detectors in wireless stations, methods have been developed during the last three years whereby these tests can be made in the laboratory more expeditiously and accurately than is possible in the regular stations. The difficulties usually encountered in laboratory tests of this kind are due mainly to the direct effect of the source of the oscillations on the receiving circuits and detector; but by using properly designed exciting circuits in connection with a buzzer as a source of oscillations these difficulties have been removed. As it is also possible in this way to produce oscillations of any required degree of damping as well as of any required wave length, all of the problems of wireless telegraphy can be successfully investigated in the laboratory except those which have to do with the properties of different types of antennae and the passage of the waves from station to station. In the following paper some experimental comparisons of the sensitiveness of wireless detectors are described.

Symbols

D = Galvanometer deflection } In general proportional to energy in detector.
A = Telephone audibility }
I = Oscillatory current. "
c = Direct current.
R = Direct current resistance.
R' = High frequency resistance.
$L_1 L_2$, etc. = Inductances.
$C_1 C_2$, etc. = Tuning condensers.
K = Large fixed condenser 0.04–0.1 mf.

[fol. 2963]

M_{34} = Mutual inductance between coils 3 and 4.
d_{12} = Distance between coils 1 and 2.
δ_1 = Logarithmic decrement in circuit I.
λ = Wave length.

Method of Experiment

The exciting circuit[1] in all the experiments is shown in Fig. 1. Here B is a buzzer run by two storage cells with considerable resistance in series. The oscillatory circuit consists of a variable air condenser C_1 having a maximum capacity of 0.005 microfarads, and for moderate wave lengths an inductance L_1 of 0.062 millihenries. These are connected directly across the contact of the buzzer.

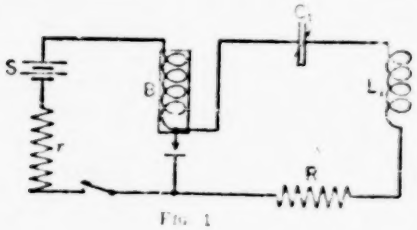

Fig. 1

The action of the circuit is as follows: When the buzzer contact is broken, the condenser C_1 is charged and this charge is retained until the contact is again closed, when the condenser discharges through the contact, producing oscillations in the circuit L_1C_1. As these oscillations take place in a closed metallic circuit, they are very feebly damped unless extra resistance is introduced at R.

All buzzers are not equally suited to producing oscillations by this method. In some, considerable adjustment of the contact is required before sharp tuning is obtained. The buzzer used in these experiments was of the 1905 United States Signal Corps type, and gave very satisfactory results with wave lengths varying between 350 and 2000 meters. With some care in adjustment the wave length could be pushed up beyond 3000. For telephonic reception of signals

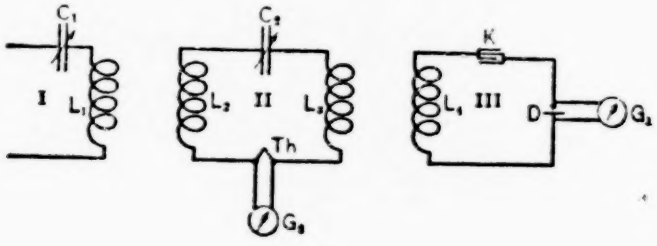

Fig. 2

[1] Other forms of buzzer circuit such as are used in several well-known types of wave meters were also tried, but with the buzzer used they gave less powerful oscillations than the one here shown.

it was usually found necessary to cut down the intensity of oscillations from the buzzer, and this was done by placing an incandescent lamp across the buzzer contact.

The chalcopyrite-zincite rectifier known as the perikon detector [2] was used as a standard for the comparison of the various detectors. As its sensitiveness varies somewhat from time to time, it was standardized before each experiment in the following manner, the circuits being shown in [fol. 2964] Fig. 2. Here *I* is the buzzer circuit, *II* a circuit containing a thermoelement of known sensitiveness, and *III* the circuit consisting of the perikon *D*, its coupling inductance L_3, and a suitable stopping condenser *K* of about 0.04 microfarad. With a given loose coupling between L_2 and L_3 the relation was noted between the reading of the galvanometer attached to the thermoelement and that attached to the perikon,[3] the condition of wave length and damping being kept constant. This relation gives at once the relative sensitiveness of the perikon. It was found better to take account of the variations in sensitiveness observed rather than to readjust each time to the same sensitiveness.

Table I shows the admirable proportionality between the deflections of the perikon detector and the square of the oscillatory current as measured by the thermoelement.

Circuit III untuned.

[2] The perikon was a new one which had been little used and was of normal sensitiveness.

[3] The resistance in the perikon galvanometer circuit must be equal to that to be used in the experiment.

Two general methods have been used for measuring the sensitiveness for telephonic reception of radiotelegraphic receivers: First, the shunted telephone method in which

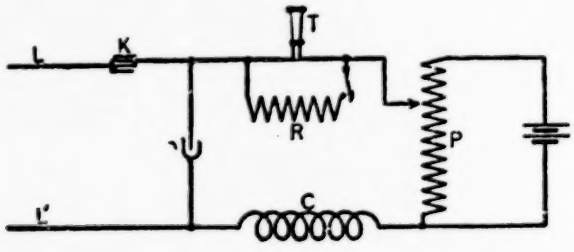

FIG. 3.

the relative loudness of response to the same signal in two different receivers can be compared, and, second, the variable coupling method by means of which the least audible signals for the different receivers can be compared.

[fol. 2965] A form of circuit for the shunted telephone method in the case of the electrolytic detector is shown in Fig. 3. Here L and L' are wires leading to the oscillatory circuit, K a stopping condenser of 0.04 microfarads capacity, T the telephones, R a variable resistance in shunt across the telephones, and C a choke coil to prevent the oscillations from running around through R instead of passing through the detector when the shunt R is closed. Two 60-ohm telephones form a suitable choke. Whatever choke coil is used it is necessary to test it by placing it across L L'. If the choke is perfect, no oscillations will pass through it, and when it is placed across L L' no change in the loudness of the signals will be observed.

The measurement of the intensity of signals is made as follows: After the receiving circuit and detector are adjusted to give maximum loudness in the telephone the shunt resistance R is closed and the resistance regulated until the signal just becomes audible. The value of the current pulses c in the telephone, which are proportional to the energy of the incoming waves in the detector, is expressed by the following well-known formula, where r is the value of the shunt, and t is the resistance of the telephones, and c' the least current audible in the telephones:

$$c = \frac{r+t}{r} c'$$

The audibility, $A = \frac{c}{c'} = \frac{r+t}{r}$

The signal is often expressed in terms of *A* as being so many times audibility. With care a series of measurements of intensity may be made to agree among themselves to within about 10 per cent.

In the variable coupling method for comparing the least audible signals in two detectors, the deflections of the galvanometer connected to the perikon are observed for a number of different degrees of coupling between the inductances L_1 and L_2. (See Fig. 2.) From these a curve is plotted which gives the variation of the received energy as determined by the distance between the coils. The coupling, for which the signals just become audible in the telephones of the detectors being compared, is then observed and the relative energy taken from the curve.

Fig. 2 shows the general plan of the circuits used in the comparison of the detectors. *I* is the exciting circuit adjusted to send out wave trains having a wave length group frequency and damping similar to those occurring in wireless practice. *II* is a circuit whose constants were made to correspond to a receiving antenna of moderate size. *III* is an untuned circuit containing a detector connected to a galvanometer or to a pair of head telephones, as the circumstances of the work required. The electrolytic, perikon, and audion were used in circuit *III*, each being so coupled to circuit *II* as to give maximum effect. The magnetic detector was placed in circuit *II*, as it is generally used in the antenna. The Fleming vacuum valve detector was coupled to *II* by its own fixed coupling coils.

[fol 2966] TABLE II. Electrolytic and Perikon detectors, shunted telephone method

[2] Wollaston wire 0.0003 mm diam.

Telephone Resistance, 813 Ohms.

Inductances, decrements, and wave length as in Table I. M_{12} adjusted for maximum sensitiveness.

The Electrolytic Detector

Comparison was made of the sensitiveness of the electrolytic detector and the perikon, using a wave length of approximately 900 meters and a decrement of the waves given out by the exciter circuit, amounting to 0.16. The values of the inductances and capacities of the circuits were so chosen that they simulated the conditions of commercial work.

In Table II are given the ratio of sensitiveness for both strong and weak signals. The perikon was used without external EMF and also with about 0.2 of a volt applied in the direction of the rectification. Comparison was made by the shunted telephone method, the same telephones being used for both detectors. In one set of experiments the telephones used were of 2100 ohms and in another of 813 ohms. The relative sensitiveness of the two detectors was little affected by this change, showing that their effective resistances must be about the same. It is seen that without external EMF the perikon is less than half as sensitive as the electrolytic, but that when the 0.2 volt is applied the difference is very small. The electrolytic used in the experiment was of the free-wire type and two positive Wollaston wires were used during the test, one 0.003 and one 0.0012 mm in diameter. This was done because it has been frequently stated that the finer wire was more sensitive to weak signals. No marked difference between the two, however, could be detected. This shows that it is only necessary for sensitiveness, that the capacity reactance for the given frequency should be large, and that beyond a certain limiting diameter there is no object in reducing the size of the positive wire.

Table III shows the relation between galvanometer deflections with the thermoelement in circuit *II* and the intensity of signals in the electrolytic in circuit *III* as meas- [fol. 2967] ured by the shunted telephone method.[1] This shows that the responses of the electrolytic as indicated by

[1] A comparison was also made of the sensitiveness of the perikon without external EMF and the electrolytic at the Washington Navy-Yard wireless station using incoming signals from a distant station. The results agreed within a few per cent with those found in the laboratory.

the telephone are proportional to the square of the oscillatory current.[5]

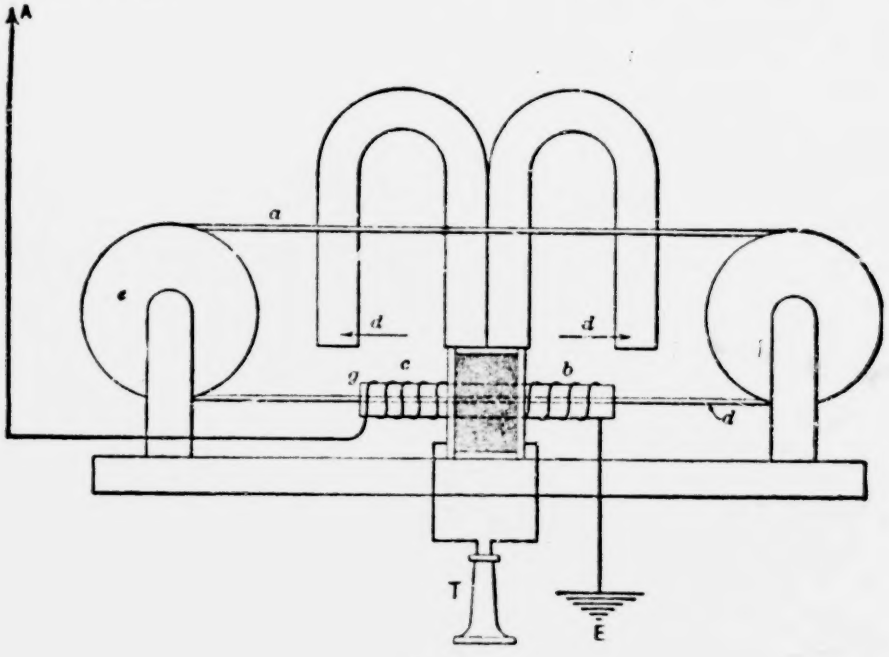

FIG. 4.

The Magnetic Detector. (Fig. 4)

The circuits for the comparison of the magnetic and perikon detectors are shown in fig. 2. The magnetic detector was connected directly in circuit *II* since it is usually used in the antenna. The magnetic detector used was of the ordinary commercial type, the D.C. resistance of the oscillatory coil being 9.7 ohms and the telephone coil 120 ohms. The

[5] Very strong signals, i.e., more than about 300 times audibility, sometimes give irregular results.

[fol. 2968] telephones furnished with the magnetic detector and used in the experiments had a resistance of 168 ohms. The telephones used with the perikon were of 1,200 ohms resistance and medium sensitiveness. For the comparison of sensitiveness the variable coupling method was used, the coupling L_1 and L_2 being changed until the signals became inaudible. When the readings on the magnetic were being taken the circuit containing the perikon was removed, then for the perikon readings the magnetic was cut out and the coupling L_1 L_3 regulated for maximum strength of signals. The relative strength of signals for the different degrees of coupling between L_1 and L_2 was determined by means of the deflection of a galvanometer attached to the perikon. Such a series of readings is shown in table IV.

$\lambda = 2000$ m

$\delta_1 = 0.16$

With waves from the buzzer circuit having a damping of 0.16 and a wave length of about 2000 meters, it was found that the magnetic detector required 2.1 times as much energy to produce an audible sound as the perikon used without external LMF.

Further experiments showed that by putting a 0.05 microfarad condenser in series with the telephone of the magnetic, thus tuning it roughly to the rate of the buzzer, the loudness of signals could be increased so that there was very little difference between it and the perikon.

TABLE V.—Magnetic and Perikon Detectors, Weak Signals.

λ	Ratio of sensitiveness: Magnetic/Perikon
350 m	0.22
900	0.9
2000	1.0
3000	1.5

Comparisons were also made at a wave length of 350 meters and at 2000 and 3000 meters. At 3000 meters the magnetic with tuned telephone was approximately one and [fol. 2969] one-half times as sensitive as the perikon. At 2000 there was very little difference, while at 350 meters the perikon was nearly five times as sensitive as the magnetic.

In order to explain these differences in relative sensitiveness, the logarithmic decrement of the circuit containing the magnetic was determined for different frequencies. For the purpose the circuits were those shown in Fig. 2, the magnetic detector being in its place in circuit *II* and the perikon with its galvanometer in the untuned circuit *III*, very loosely coupled to *II*, so that no appreciable energy was taken up by it. The buzzer exciter circuit was adjusted so as to give feebly damped oscillations having a decrement of about 0.02. The decrement of circuit *II* was determined from the well-known formula

$$\delta_I + \delta_{II} = \pi \frac{C_m - C}{C_m} \sqrt{\frac{I^2}{I_m^2 - I^2}}$$

where C_m represents the reading of the condenser in circuit *II* for resonance and C any other reading slightly removed from resonance. I_m then represents the value of the oscillatory current for resonance and I that for the setting of the condenser at C. This formula becomes much more convenient in practice if we choose I^2 so that it is just one-half I_m^2, for then the expression under the radical reduces to unity. As the deflection of the galvanometer connected to the perikon is proportional to I^2, our expression becomes

$$\delta_I + \delta_{II} = \pi \frac{C_m - C}{C_m}$$

where the change from C_m to C, either an increase or a decrease, is just sufficient to reduce the deflection of the galvanometer to one-half. The mean of several determinations of $C_m - C$ gives as accurate values for the decrement as can be obtained from a curve plotted in the usual manner and calculated according to the complete formula. In damping experiments it is necessary that all the couplings be made so loose that any further loosening will not decrease the value of the damping.

TABLE VI.—Effective resistance of magnetic detector at different wave lengths

λ	R'

3000	10

TABLE VII.—Received energy and audibility of signals in magnetic detector

Perikon D	Magnetic A
300 mm	120
80	53
55	40
20.5	16.5
7.5	10
2.0	2

[fol. 2970] δ' having been previously measured, the effective resistance R' of the circuit containing the magnetic detector was calculated from the formula

$$R' = 2\pi L \delta_{II}$$

where δ_{II} is the decrement, ν the frequency, and L the inductance of the circuit. After subtracting the known ohmic high frequency resistance of the circuit, the other losses due to the detector for the different frequencies are shown in Table VI. This table would indicate that the amount of iron and the number of turns of the oscillatory circuit of the magnetic detector should be varied according to the frequency for which it is to be used.

In Table VII is shown the relation between loudness of signal as determined by the shunted telephone method in the magnetic and the oscillatory energy passing through it as determined by the deflections of the perikon galvanometer. It is seen that the loudness of signal in the telephone attached to the magnetic is not proportional to the square of the oscillatory current, but corresponds more nearly to the 1.4 power.

The Fleming Vacuum Valve Detector. (Fig. 5)

The vacuum valve detector furnished for the test was constructed with fixed coupling coils inclosed in its case, so that it was found impossible to test it fairly at any except very short wave lengths without taking it completely to pieces.

The circuits were arranged as shown in Fig. 2, the vacuum valve being coupled by its own coils to circuit *II*. Signals were taken alternately on the perikon, adjusted for maximum strength of signal, and on the vacuum detector, one

detector circuit being removed when the other was in action. At a wave length of 350 meters and with a decrement of the incoming signals of 0.16, the ratio of sensitiveness of the perikon to that of the vacuum detector, as determined by the variable coupling method, was almost exactly two to one. For a wave length of 900 meters the perikon appeared to be at least ten times as sensitive as the vacuum valve. As there is no reason to believe that the vacuum detector would change its sensitiveness with frequency, this difference is almost certainly due to insufficient coupling.[6] [fol. 2971] In Table VIII is given the relation between oscillatory energy in the main circuit and the audibility of signals in the telephone of the vacuum detector, as determined by the shunted telephone method. The audibility is seen to be proportional to the energy. The telephones furnished with the vacuum detector had a resistance of 8300 ohms and were connected by means of a step-in transformer to the detector circuit.

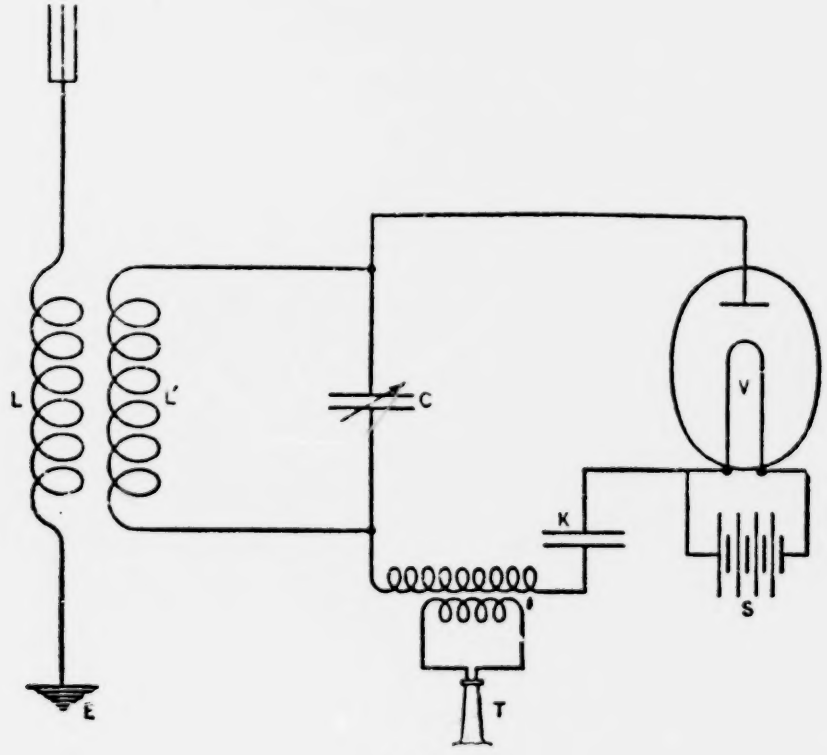

Fig. 5.

[6] This shows the disadvantage of constructing receiving apparatus with fixed coupling.

TABLE VIII.—*Received energy and audibility of signals in Fleming vacuum detector.*

10	9
5	5

The Audion. (Fig. 6)

The De Forest form of vacuum detector, called by him the audion, is shown diagrammatically in Fig. 6. Here V is an exhausted glass bulb containing a tantalum filament F, heated by three storage cells S, a metal plate P and a metal grid G between the filament and the plate. The filament and plate are connected externally through a battery B

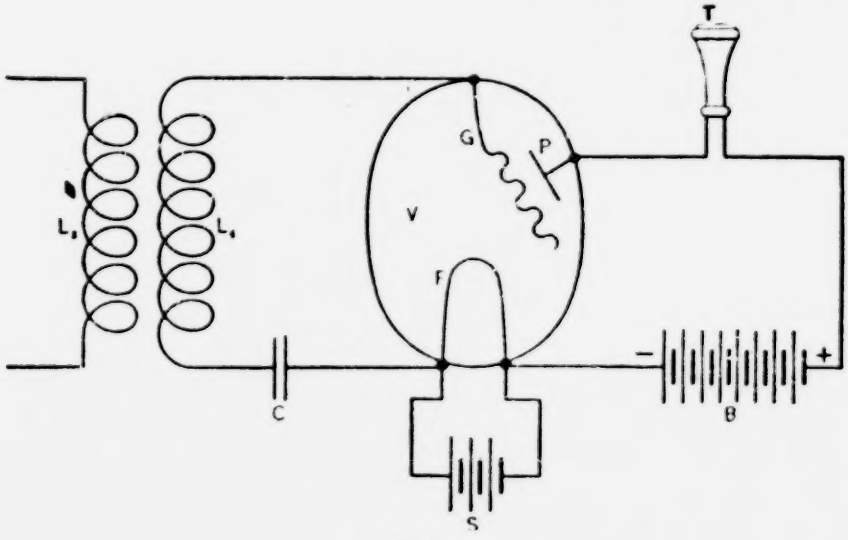

Fig. 6

[fol. 2972] of 36 small cells, any number of which can be thrown into the circuit, and a pair of head telephones of about 1200 ohms resistance. The filament and grid are connected through a small fixed condenser C and an inductance L_2 which is coupled to the oscillatory circuit.

The action of the detector appears to be as follows: The heated filament F is charged negatively by the battery B and a steady stream of negative electrons flows from the hot filament to the cold plate producing a direct current through the telephone. When an oscillatory electromotive force is impressed on the circuit $F\ L_2\ G$, the negative current can flow from F to G inside the bulb and not in the reverse direction, just as in the Fleming detector. The grid G thus

becomes negatively charged and as it lies between F and P the direct current through the telephone is decreased as may be shown by placing a galvanometer in the telephone circuit.

The sensitiveness of the audion was compared with that of the electrolytic already described by the varying coupling method. (See Fig. 2.) Here L_3 and L_4 were the primary and secondary of a Wireless Specialty Apparatus Company tuner, the secondary condenser of the tuner being detached. The detectors were introduced alternately in circuit *III* and their most favorable conditions of coupling were determined separately. The audion, having a higher resistance, required a stronger coupling. The same telephones (1200 ohms) were used for both detectors, previous tests having shown that they were suited to each. High-resistance telephones up to 8000 ohms were tried with the audion, but were found to be less satisfactory than the ones used. This is remarkable, as with the Fleming vacuum detector 8000-ohm telephones are used and even then the current is stepped down through a transformer.

[fol. 2973] Below are given the data of the experiment:

λ=900 m., δ_3=0.3, L_1=0.062, L_2=0.03, L_3=0.705, L_4=0.92 m. h. (electrolytic). L_4=2.3 (audion).

Electrolytic coupling L_3 L_4=7 cm on coupling scale[7] of tuner; audion coupling =2 cm. Distance between coils L_3 L_4 for least audible signal, 20.5 cm (electrolytic); 23 cm (audion).

Ratio of energy sensitiveness $\frac{\text{audion}}{\text{electrolytic}}$ 1.5. Some of the bulbs were slightly more sensitive than this when first tried, but the sensibility decreased with use.

The law governing the relations between the intensity of the oscillations and the loudness of response in the telephone, as determined by the shunted telephone method, seems to depend on the impressed direct electromotive force from the battery B and also on the temperature of the filament F, as would be expected from the known form of the current voltage curve in the case of the passage of electricity from a hot to a cold body through a gas. For most adjustments the response of the telephone is apparently nearly proportional to the square of the oscillatory current.

[7] The numbers on the scale represent the distance the two coils are drawn apart from the position of maximum mutual inductance.

In addition to the above detectors, a very large number of other types have been tested in the laboratory, among which are the tellurium, silicon, and carbon already described,* and also many crystal detectors. These detectors are all of the rectifying type and are remarkable in that when properly adjusted and used with telephones of proper resistance, and in some cases with small EMF in the direction of the rectification, they all give practically the same sensibility as the perikon. The usefulness of several of these is, however, limited by the difficulty of adjustment and a lack of constancy. In most of these detectors the loudness of the signal increases nearly in proportion to the square of the oscillating current, although in some of them the increase in loudness is less rapid.

United States Naval Wireless Telegraphic Laboratory, March 1, 1910.

Defendant's Exhibit G-1

Practical Wireless Telegraphy, by Bucher, 1918

Like the carborundum detector, the Fleming valve has a rising characteristic and when an E. M. F. is applied to the space between the plate and the filament the current may be adjusted to the critical point on the characteristic curve so that the addition of a slight antenna voltage causes a large increase of the local battery current flowing through the head telephones.

A satisfactory diagram appears in Fig. 162 wherein a potentiometer P-1 is shunted across the filament battery and a portion of the current flows through the head telephones and the detector. With this arrangement of circuits advantage is taken of the particular voltampere characteristic of the valve and a relay action due to a local [fol. 2974] source of energy is obtained. For the maximum strength of signals with this circuit it is necessary to adjust the position of the sliding contact on the potentiometer as well as the incandescence of the filament, until the desired results are obtained.

The diagram, Fig. 162, shows the fundamental circuit of the widely used *Marconi-Fleming valve receiver*. The *open circuit* comprises:

* This Bulletin, Vol. 5, No. 1, p. 153; 1908.

(1) The aerial tuning inductance L-1,
(2) The short wave condenser C-1,
(3) The primary winding L-2,
(4) The shunt impedance R-1,
(5) The change-over switch S-1, S-2, S-3.

The *intermediate circuit* comprises:

(1) The winding L-3 in inductive relation to L-2,
(2) The winding L-4 in inductive relation to L-5,
(3) The variable condenser C-2.

The *secondary circuit* comprises:

(1) The secondary winding L-5,
(2) The billi condenser C-3,
(3) The Fleming valve F, P,
(4) The battery B (or four volts generally),
(5) The 10 ohm rheostat R,
(6) The 400 ohm potentiometer P-1,
(7) The fixed condenser C-4,
(8) The head telephone P-2.

Inductances L-2, L-3, L-4, L-5, L-6 are of fixed value, but L-1 is variable through the medium of a multi-point switch.

When the D. T. three blade switch S-1 is thrown to the right, primary winding L-2 is connected in series with the *aerial circuit* which brings the *intermediate circuit* into use, but the switch, thrown in the opposite direction, disconnects L-2 and connects L-6 in series with the aerial. L-6 being wound tightly about the turns of L-5, the open and closed circuits are closely coupled. *This increases the damping of the receiving system* and makes the set responsive to waves of different length at one set

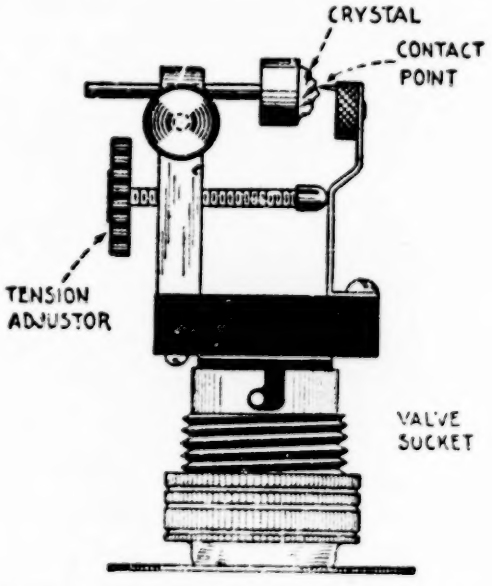

FIG. 163.—Carborundum Crystal Holder to Fit Fleming Valve Socket.

of adjustments, but, of course, does not give the strength of signals that can be obtained by resonant adjustments.

The position of the switch corresponding to "*close coupling*" is marked "Stdbi," an abbreviation for the word [fol. 2975] "standby." The switch is placed in this position when a particular receiving station awaits a call from one of several sending stations which are not exactly tuned to the same wave length.

In the opposite position, the changeover switch is marked "*tune*" and with the circuits of this connection, sharp resonant adjustments can be obtained. The wave length of the *intermediate circuit* is increased or decreased by the variable condenser C-2 only and similarly the wave length

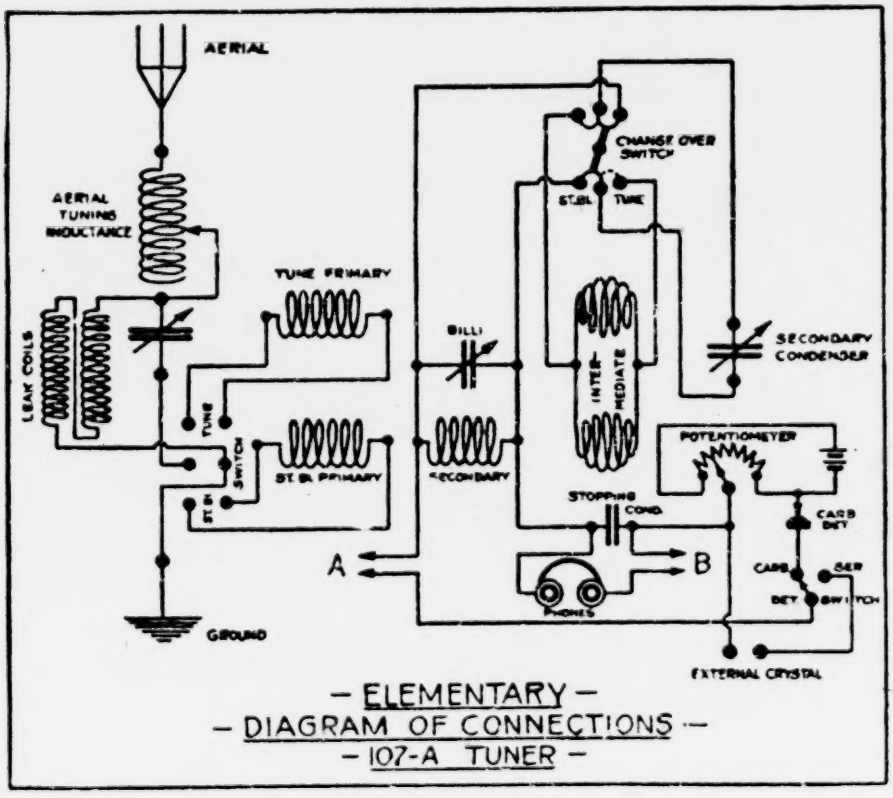

FIG. 164.—Complete Circuits of Type 107a Tuner (American Marconi Company).

of the secondary or detector circuit, by the condenser C-3.

The coupling between the inductances of the intermediate circuit and inductively related coils is varied simultaneously by means of a shaft (and knob) upon which both coils, L-3 and L-4, are mounted.

The impedance coil R-1 prevents the accumulation of high voltages upon the dielectric of the variable condenser, which may be punctured in case the windings of the tuner should come in direct contact with the high voltage wires of the transmitting apparatus.

The American Marconi Company has developed a crystal holder to fit in the Fleming valve socket as shown in Fig. [fol. 2976] 163. The circuit for the crystal detector is practically identical with that of the oscillation valve with the exception that the lighting battery is connected to the potentiometer instead of to the lamp filament.

The vaive tuner was original- designed to be responsive to waves varying between 300 and 1,650 meters in length, but the circuit has been modified to respond to waves up to 2,500 meters, as in Fig. 164.

136. *Marconi Type 107-a Tuner.* (*American Marconi Company*).—The various connections and arrangements of circuits of the Marconi type 107-a tuner are shown in Figs. 165-a, 165-b and 165-c. The principal change over the ordinary valve circuit lies in the special six point double throw switch (marked "*change-over switch*") which disconnects the condenser of large capacity (.01 microfarads) across the *intermediate circuit* and places it in shunt to the secondary winding and the *billi-condenser* (see Fig. 165-a). With the increased capacity of this condenser in shunt, the secondary circuit will respond to a wider range of wave

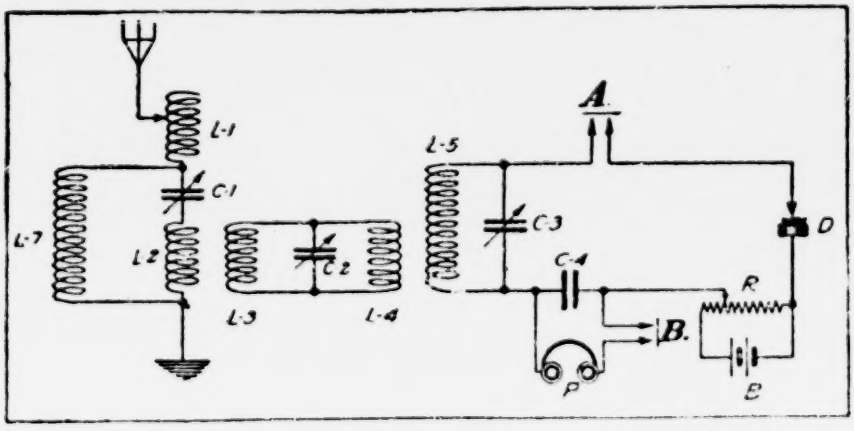

Fig. 165a.—"Standby" Long Wave Adjustment of Marconi Type 107a Tuner.

lengths than the original design of the tuner would permit.

For the reception of wave lengths exceeding 1,500 meters,

the D.P.D.T. switch is thrown to the "*standby*" position and the intermediate circuit cut out. For wave lengths below 1,000 meters either the "*standby*" or "*tune*" circuits can be employed at the discretion of the operator.

It is to be noted, although the 107-a tuner is designed for the carborundum detector, an extra set of posts is provided for an additional crystal such as *crusite*. When the latter detector is employed, the potentiometer is out of the circuit. Observance next should be made of the binding posts from which wires are connected to the receiver circuits and to the contacts of an aerial change-over switch. The latter, when open, protect the detector and head telephones from the induced potentials of the local transmitter. [fol. 2977] In the diagram, Fig. 165-b, L-1 is the aerial tuning inductance, the value of which is altered by means of a multi point switch mounted on the left hand front of the tuner.

C-1 is the short wave variable condenser connected in series with the aerial system. In the full scale position it short circuits itself and is thus cut out of the antenna circuit. This condenser is mounted on the left hand side on the top of the tuner.

L-2 is the primary winding of the receiving tuner and has a fixed value of inductance (not variable).

. . . . . .

The complete circuit for this connection is indicated in Fig. 165a. Note carefully that the intermediate circuit is *not* employed. It is important to note also that the type

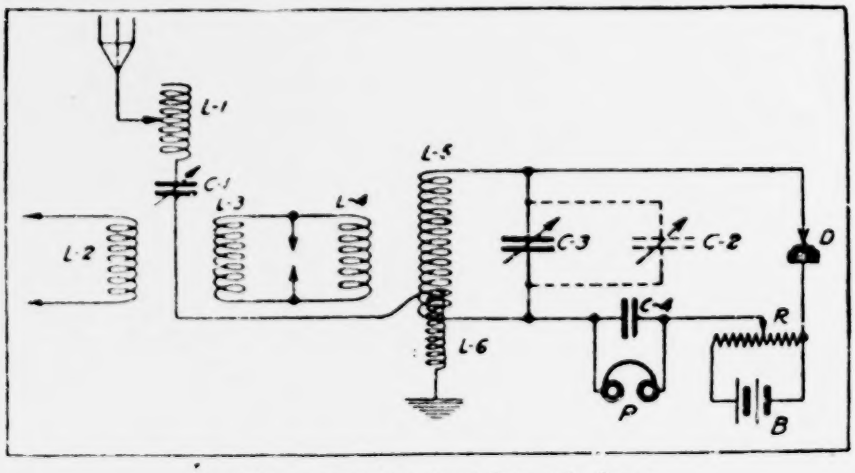

Fig. 165b. "Tune" Circuits of Type 107a Tuner

107-a tuner is fitted with four binding posts (at the rear) from which connections extend to the type S aerial changeover switch. When the antenna switch is placed in the transmitting position, the circuits of the 107-a tuner are interrupted at the points A and B (Fig. 165b), thus breaking the circuit to the detector and the head telephones. The contacts at this switch must have careful inspection from time to time, for, unless they close properly, the apparatus positively will not function.

Should these contacts be broken, a permanent jumper should be placed across the binding posts to keep the circuit closed.

Type 107-a tuner should be used with the type S or type I aerial changeover switches only.

The complete circuits for the tuner are shown in detail in Fig. 165a and with the foregoing explanation, the functions of the various elements should be clear without further instruction.

(c) *General Instructions.*—For "*stand-by*" *tuning or broad adjustment* at wave lengths up to 1,000 meters (see Fig. 165c), place the double throw knife switch to the left.

Set the condenser switch on "tune." Set the coupling knob at zero. Carefully adjust the billi condenser. Con- [tol. 2978] nect in a few points of the aerial tuning inductance. Vary the capacity of the short wave condenser.

For long wave lengths (in excess of 1,000 meters) place the condenser switch on "stand-by long wave" position. Vary carefully the capacity of the intermediate condenser. Add inductance at the aerial tuning inductance.

For *sharp tuning on the shorter wave lengths* (below 1,000 meters), place the double throw knife switch to the "tune" position. Place the condenser switch on the "tune" position. Set the coupling knob at from 70° to 90°. Adjust carefully the intermediate condenser. Add two or three points of inductance at the aerial tuning inductance. Follow this by variation of the capacity of the short wave condenser. In this position, all the variable elements of the complete tuner are in use.

137. *Marconi Magnetic Detector and the Multiple Tuner Circuits (English Marconi Company).*—The magnetic detector shown diagrammatically in Fig. 167 is an oscillation

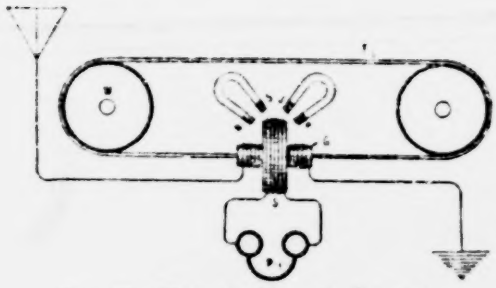

Fig. 167. Marconi's Magnetic Detector

detector of unvarying stability. A description of the detector and an explanation of its functioning follow:

A continuous *band* made up of a group of fine *iron wires* revolves on the *ebony grooved wheels* W which are turned by clockwork in the base of the instrument. The band passes through the *glass tube* G, which has a small single layer of fine wire comprising 6 to 10 turns through which the radio frequent oscillations flow. Directly over this winding is placed the *small bobbin of wire* S which has approximately the resistance of the head telephones P-1. Two *horse-shoe permanent magnets* with like poles adjacent are mounted immediately above the tube and near to it. Some argument exists concerning the action of this detector during the reception of signals but it is sufficient to say that when the iron band passes underneath the two permanent magnets it undergoes a cyclic change in magnetism and is extremely sensitive to an impressed external magnetic field such as that generated by a radio frequent current flowing through the winding G.

When electrical oscillations induced in a receiver aerial by a distant transmitter pass through the winding P, one complete group of oscillations sets up an alternating magnetic field which causes a single movement or a change in the position of the flux in the iron band. The bobbin S being in the path of the flux, it is acted upon inductively, a current being induced in the windings which flows through the head telephone creating a single sound for each group of incoming oscillations. The note of the transmitter is faithfully reproduced, because each group of oscillations radiated by [fol. 2979] the transmitter has a cumulative effect on the change of flux in the iron band, which causes a single movement of the telephone diaphragm. Although the magnet detector lacks the sensitiveness of the crystal

. . . . . .

It has frequently been observed that the magnetic detector gives better response to 500 cycle transmitters when the iron band revolves at a speed about twice that used in receiving from 60 cycle transmitters. Normally the band travels at a very low speed—a few feet per minute.

* * * * * * *

138. *The Marconi Type 106 Receiving Tuner. (American Marconi Company).*—A receiving set of particular excellence combining mechanical and electrical features of merit is the type 106 tuner of the American Marconi Company. This set is of the panel type, the necessary controlling switches being mounted on the front of the board as shown in photograph 170, the coupler, variable condensers, potentiometer, etc., being mounted on the rear as in photograph 171. The *coupling* between the primary and secondary windings is varied by means of a special *rack and pinion adjustment* which is in turn controlled by a knob on the front of the panel with a scale marked from zero to 10 (marked "coupling").

The switch marked "*transformer secondary*" and the control handle marked "*secondary condenser*" control the inductance and capacity of the secondary circuit. The wave length adjustment of the circuit can be increased by turning the switch or the knob of the condenser counter clockwise. Different values of inductance and capacity can be employed in this circuit while holding the same wave length. This changes the damping of the circuit and proper proportioning (of inductance and capacity) may give increased strength of signals during the reception of signals from certain stations.

The control handle marked "*potentiometer*" varies the flow of current through the detector crystal. Close adjustment of the potentiometer is necessary when the incoming signals are comparatively weak. The switch marked "*battery*" turns the local battery current on and off.

The terminals marked "*battery*" connect to four dry cells in a separate box and the terminals marked "*telephones*" are the binding posts for connection to 2,000 ohm receivers.

As the transmitter operates at approximately the wave length to which the secondary circuit of the receiver is adjusted, it produces exceedingly strong signals which are liable to impair the sensitive condition of the crystal. To obviate this, connections are made with the antenna switch so that when the antenna switch is in the transmitting position the terminals of the detector and the secondary condenser are short-circuited. Care should be taken to see that the antenna switch, with which this receiver is to be used, is so constructed as to perform the above operations. If [fol. 2980] this is done, the transmitter has very little or no effect on the sensitiveness of the crystal and it will, therefore, be in a sensitive condition for receiving immediately after transmission. (See diagrams, Figs. 201, 202 and 203.) In addition to paragraph 130 the student should read the general instructions in paragraph 156a.

139 *Marconi Receiving Tuner Type 101 (American Marconi Company).*—The type 101 receiver consists of an inductively coupled transformer with two solid rectifier detectors and the necessary accessory apparatus mounted on a hard rubber panel and enclosed in a mahogany case. The front elevation of this set is shown in photograph, Fig. 173, the rear elevation in Fig. 174, and a fundamental diagram in Fig. 175.

The aerial is connected to the binding post "antenna" and the earth connection is made to the binding post marked "ground." The circuit between these two points is adjusted to resonance with the incoming signal by variation of the two transformer primary switches, the primary loading coil switch, the primary condenser, and the primary condenser switch which is marked "out" "series" and "shunt." The purpose of this switch is to connect the primary condenser in series or in parallel to the aerial or to disconnect the condenser entirely.

* * * * * * *

Placing the primary condenser switch in the "Shunt" position increases the wave length of the aerial circuit corresponding to any given setting of the inductance switches. This may be done at any time instead of increasing the inductance. Generally speaking, the method of varying inductance is preferable and gives a louder response, but in

exceptional cases the reverse is true and in any particular case a trial of the two methods can be made to find out which is the better. The best secondary setting for maximum response to any particular wave length is that of maximum inductance and minimum capacity, but the greatest selectivity will be obtained with smaller inductance and greater capacity.

When the carborundum detector is in use it will be necessary to adjust the potentiometer to a point which gives the greatest sensitiveness.

It should be noted that when using the Cerusite detector during the reception of very weak signals the potentiometer should always be in zero position, but for signals of moderate intensity it does not matter particularly what position this may happen to be in. In order that the operator may be able to measure approximately the wave length of the incoming signals, calibrations of the secondary are given with each tuner, it being understood that these are correct only when the secondary is coupled very loosely to the primary.

With the 101 receiver are supplied adjustable head telephones which are tuned to the group frequency of the transmitter. Also the electrical circuit through the telephones and the stopping condenser is tuned to the same group frequency.

[fol. 2981] It is advisable occasionally to insert a piece of paper between the spark points of the antenna and ground binding posts and telephone binding posts to make sure they are not short-circuited.

140. *The Marconi Universal Receiving Set (English Marconi Company).*—The complete circuits of the Universal Crystal Receiver are indicated in the diagram, Fig. 176, and a photograph of the finished instrument in Fig. 177, the tuner having been designed for wave lengths between 300 and 3,000 meters. The circuits are applicable to all types of crystal rectifiers, particularly those of carborundum, zincite, bornite, etc.

* * * * * * *

The usual aerial tuning inductance is represented at L 1, the short wave condenser at C 1, and the primary winding of the *tuning transformer* at L 2. L 2 has three tappings,

which are varied by means of the switch. The secondary circuit of the receiving tuner is divided into three units, the following range of wave lengths being obtained with each: L-5 has the correct values for all wave lengths up to 600 meters; L-4 for waves between 600 and 1,600 meters, and L-3 for waves between 1,000 and 3,000 meters. The necessary change of inductance is obtained by the wave length changing switch D, which completely disconnects the unused turns from the circuit.

. . . . . .

154. *The Marconi Balanced Crystal Receiver (English Marconi Company).*—No apparatus or circuit has so far been devised to completely eliminate the interference of static discharges. However, communication can be effected by the circuits of the Marconi balanced crystal receiver when with ordinary circuits it would not be possible. In fact, the balanced crystal tuner often reduces the interference from this source to a marked degree.

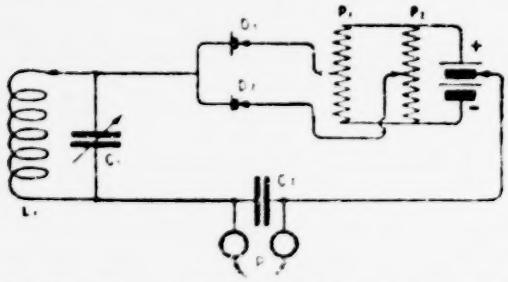

Fig. 198.—Circuits of Marconi's Balanced Crystal Receiver. (English Marconi Company.)

The complete circuits of the balanced crystal receiver are shown in the diagram, Fig. 198, where the secondary winding of the receiving tuner is represented by the coil L-1, the secondary condenser at C-1, the opposed crystals at D-1 and D-2, the potentiometer at P-1 and P-2, the battery at B and the telephones at P.

To carry out the fundamental principle of this receiver, crystals D-1 and D-2 must have like volt-ampere characteristics, and, accordingly, crystals are especially selected for the purpose.

Briefly, the action of this circuit can be described as follows: If crystals D-1 and D-2 are adjusted to the same degree of sensitiveness their currents will act equally and oppositely upon the telephone P, and no signals will result. If, however, D-2, let us say, is adjusted to a high degree of [fol. 2982] sensitiveness and D-1 to a lesser degree, signals will be received.

Under these conditions, if an extra severe discharge of static excites the aerial circuit, almost equal effects are

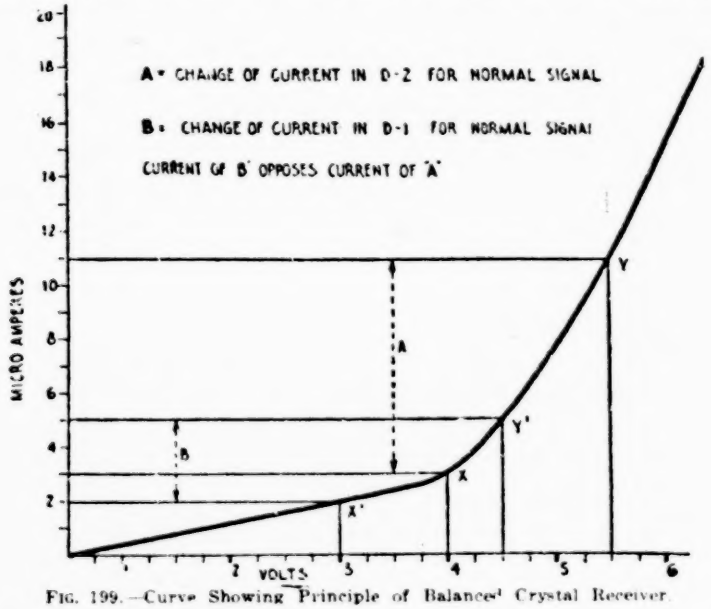

FIG. 199.—Curve Showing Principle of Balanced Crystal Receiver.

produced in the head telephone P by both crystals, and the crashing sounds ordinarily experienced are partially eliminated.

• • • • • • •

steel bar F closes the circuit to the primary winding of the power transformer through the contacts 11 and 12. In the opposite position the bar separates the spring contacts M, M' 200–a, which disconnects the transmitting oscillation transformer from the aerial during the period of reception, preventing the incoming oscillations leaking to earth. *The various circuits closed by the discs mounted on the hard rubber rod place the detector and head telephone on short circuit during the period of transmission. They may also be employed to start and stop a motor blower or an automatic motor starter.* The type I switch is supplied with Marconi transmitting sets up to 5 K.W. capacity.

For the use of operators in the Marconi service, the circuit diagrams, Figs. 201, 202, and 203, are published, showing the connections in Fig. 201 of the type I antenna switch to the external binding posts of the type 106 receiving tuner, and in Fig. 202 the connections of the type S, H, aerial changeover switch to the external binding posts of the type 106 tuner. The diagram, Fig. 203, shows the connections

of the type I antenna switch to the external binding posts of the type 107-a receiving tuner.

[fol. 2983] In the diagram, Fig. 201, binding posts 2, 4, and 5 of the type I antenna switch short circuit the crystal detector and the head telephones during transmission. Binding post No. 1 connects to aerial binding post No. 1 of the type 106 tuner. Contacts 11 and 12 close the circuit to the primary winding of the transformer. The binding posts 6, 7, 8, and 9 of the type 106 tuner are connected to the four binding posts of the battery box as shown.

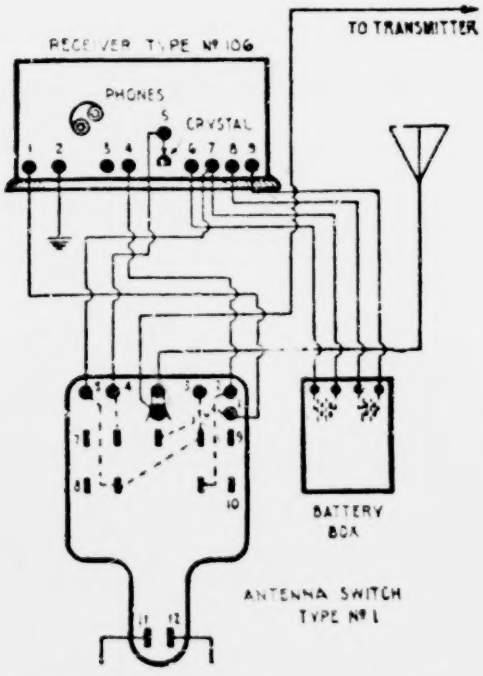

Fig. 201. Type I Switch Connected to Type 106 Receiving Tuner.

In the diagram, Fig. 202, posts 1, 2, 4 and 5 of the type S. H. antenna switch lead to contacts which place the head telephone and detector of the type 106 tuner on short circuit. Binding posts 11 and 12 close the circuit to the primary winding of the transformer.

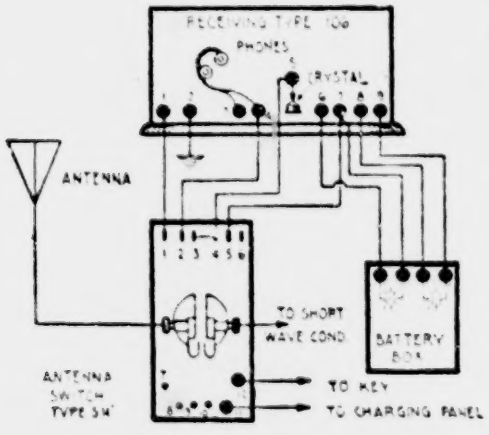

Fig. 202. Type S. H. Switch Connected to Type 106 Receiving Tuner.

In the diagram, Fig. 203, posts 2, 4, and 5 of the type I switch lead to contacts which short circuit the receiving detector and the receiving telephones. These diagrams should be carefully studied and in event that the wiring is taken down, the connections shown should be carefully duplicated.

156. *Type 112 Receiving Tuner.*—This receiving tuner was primarily de-

signed for use with the special ¼ K.W. cargo type transmitter developed by the Marconi Company and fundamentally is similar to the type 101 and type 106 tuner, but the construction is considerably simplified. A front view is shown in Fig. 203-a and a side view in Fig. 203-b.

As will be seen in the wiring diagram, Fig. 203-c, the circuits are similar to those shown in Fig. 153-b, the potentiometer, battery, and head phones being shunted.

[fol. 2984] DEFENDANT'S EXHIBIT H-1

Proceedings of Institute of Radio Engineers, August 1916

The receiver used with these sets is of the coupled circuit type and is known as the type "106" receiver. There are two circuits in this receiver, the one circuit known as the open or antenna circuit, and the other as the closed tuned circuit. These two circuits are coupled inductively and means are provided for varying the inductive relation of the two circuits. The primary circuit consists of the antenna, a loading coil, a primary coil, a series condenser, and a ground connection, all being connected in series. By means of a switch any amount of the loading coil in the primary can be thrown into circuit at will. This enables the operator to adjust readily this circuit to the received signals. In case the wave length of the received signal is shorter than the natural period of the antenna, the series condenser is thrown in the circuit which brings this circuit to the desired period. The secondary circuit consists of a secondary coil or inductance which is movable with respect to the primary. This coil is in series with a variable condenser. A switch is provided which permits any amount of the secondary to be thrown in the circuit. The variable condenser permits the variation of the capacity of this circuit so that it may be adjusted for resonance with the primary circuit. By having both the inductance and capacity of this circuit variable, the ratio of capacity to inductance can be varied while keeping the period of the circuit constant. This enables the operator to obtain the best adjustment for operating the detector. The detector used in this receiver is of the crystal type. A battery and potentiometer are provided so that a crystal can be operated either with or without battery as desired. The detector circuit consists of the potentiometer, a stopping condenser and the telephones. The

potentiometer and stopping condenser are connected in series with each other and in shunt to the variable condenser. The telephones are connected in shunt with the stopping condenser. A test circuit is provided which enables the operator to excite the antenna circuit at will so that he can adjust the detector for maximum sensitiveness. These circuits are all shown in Figure 4. A careful consideration of this drawing will enable the reader to understand fully the complete circuits of both transmitter and receiver.

families are also comparatively few. The families so contributing are, however, among the most important and widely distributed in the vegetable kingdom; as also are some of the plants they contribute. As prominent examples may be mentioned, the *Gramineæ*, affording the cereal grains, a large proportion of the mixed herbage of grass-land, and other products; also the *Leguminosæ*, yielding pulse crops, many useful herbage plants, and numerous other products. As we have said, there does not seem to be an unsolved problem as to the sources of the nitrogen of other of our agricultural plants than those of the leguminous family. Obviously, however, it would be unsafe to generalise in regard to individual families as a whole, from results relating to a limited number of examples supplied by their agricultural representatives alone. Still, there is nothing in the evidence at present at command, to point to the supposition that there is any fundamental difference in the source of the nitrogen of different members of the same family, such as is clearly indicated between the representatives of the leguminous, and of the other families, supplying staple agricultural products. On the other hand, existing evidence does not afford any means of judging whether or not similar, or allied agencies to those now under consideration, or even quite different ones, may come into play in the nitrogen assimilation of the members of other families which contribute such a vast variety of vegetation to the earth's surface.

We have pleasure in stating that the conduct of the investigation has largely devolved upon Dr. N. H. J. Miller. He has been almost wholly responsible for the analytical work, as well as for the photographing, by which a permanent record, not only of the above-ground growth, but of the root-development of the experimental plants has been secured. It should be added, that Mr. J. J. Willis has materially assisted in the observation and noting on growth; also in the separation of the roots, mounting them for observation and for photographing, and in noting upon them.

II. "On Electric Discharge between Electrodes at different Temperatures in Air and in High Vacua." By J. A. FLEMING, M.A., D.Sc., Professor of Electrical Engineering in University College, London. Communicated by Professor G. C. FOSTER, F.R.S. Received December 16, 1889.

(Preliminary Notice.)

It has been known for some time that if a platinum plate or wire is sealed through the glass bulb of an ordinary carbon filament incandescent lamp, this metallic plate being quite out of contact with

2985½

the carbon conductor, a sensitive galvanometer connected between this insulated metal plate enclosed in the vacuum and the external *positive* electrode of the lamp indicates a current of some milliampères passing through it when the lamp is set in action, but the same instrument when connected between the *negative* electrode of the lamp and the insulated metal plate indicates no sensible current. This phenomenon in carbon incandescence lamps was first observed by Mr. Edison, in 1884, and further examined by Mr. W. H. Preece, in 1885.* The primary object of the experiments described in this paper was the further examination of this effect, but the inquiry has extended itself beyond this range and embraced some general phenomena of electric discharge between electrodes at unequal temperatures, and in particular has revealed some curious effects in the behaviour of an electric arc taken between carbon poles towards a third insulated carbon or metal poles.

The first series of experiments had reference to the nature of the effect observed in the incandescence lamps having an insulated wire or plate placed in the vacuum.

If a platinum wire is sealed through the glass bulb of an ordinary carbon filament lamp and carries at its extremity a metal plate, so placed as to stand up between the legs of the carbon horseshoe without touching either of them, then when the lamp is actuated by a continuous current it is found that :—

(1.) This insulated metal plate is brought down instantly to the potential of the base of the negative leg of the carbon, and no sensible potential difference exists between the insulated metal plate and the negative electrode of the lamps, whether the test be made by a galvanometer, by an electrostatic voltmeter, or by a condenser.

(2.) The potential difference of the plate and the positive electrode of the lamp is exactly the same as the working potential difference of the lamp electrodes, provided this is measured electrostatically, *i.e.*, by a condenser, or by an electrostatic voltmeter taking no current.

* See 'Roy. Soc. Proc.,' vol. 38, 1885, p. 219. "On a Peculiar Behaviour of Glow Lamps when raised to High Incandescence."—In this paper Mr. Preece describes a very careful series of observations carried out with Edison incandescence lamps, and which cover the same ground as a portion of the experiments here described. The results given in (4), (7), and (11) confirm the facts which were first ascertained by him. He also arrived at the general conclusion that the phenomena so observed are due to an electric convection by matter projected from the incandescent carbon. By carrying up the working electromotive force of the lamp to a point productive of very high incandescence, he was able to measure the resulting current through a galvanometer connected between the positive lamp electrode and the middle plate corresponding to every degree of incandescence, and showed that, whilst increasing up to a certain point, the galvanometer current fell off rapidly soon after a certain critical temperature was reached, which corresponded to the appearance of a blue light or haze in the glass receiver.—[Jan. 14th, 1890.]

but if measured by a galvanometer the potential difference of the plate and the positive electrodes of the lamp is something less than that of the working lamp electrodes.

(3.) This absolute equality of potential between the negative electrode of the lamp and the insulated plate only exists when the carbon filament is in a state of vivid incandescence, and when the insulated plate is not more than an inch or so from the base of the negative leg. When the lamp is at intermediate stages of incandescence, or the plate is considerably removed from the base of the negative leg, then the plate is not brought down quite to the same potential as the negative electrode.

(4.) A galvanometer connected between the insulated plate and the *positive* electrode of the lamp shows a current increasing from zero to four or five milliampères, as the carbon is raised to its state of commercial incandescence. There is not any current greater than 0·0001 of a milliampère between the plate and *negative* electrode when the lamp has a good vacuum.

(5.) If the lamp has a bad vacuum this inequality is destroyed, and a sensitive galvanometer shows a current flowing through it when connected between the middle plate and either the positive *or* negative electrode.

(6.) When the lamp is actuated by an *alternating* current a *continuous* current is found flowing through a galvanometer, connected between the insulated plate and *either* terminal of the lamp. The direction of the current through the galvanometer is such as to show that negative electricity is flowing from the plate through the galvanometer to the lamp terminal. This is also the case in (4); but, if the lamp has a bad vacuum, then negative electricity flows *from* the plate through the galvanometer *to* the positive terminal of the lamp, and negative electricity flows *to* the plate through the galvanometer from the negative terminal of the lamp.

(7.) The same effects exist on a reduced scale when the incandescent conductor is a platinum wire instead of carbon filament. The platinum wire has to be brought up very near to its point of fusion, in order to detect the effect, but it is found that a current flows between the positive electrode of a platinum wire lamp and a platinum plate placed in the vacuum near to the negative end of that wire.

(8.) The material of which the plate is made is without influence. Platinum, aluminium, and carbon have been indifferently employed.

(9.) The active agent in producing this effect is the *negative* leg of the carbon. If the negative leg of the carbon is covered up by enclosing it in a glass tube this procedure entirely, or nearly entirely, prevents the production of a current in a galvanometer connected between the middle plate and the positive terminal of the lamp.

(10.) It is a matter of indifference whether a glass or metal tube is

employed to cover up the negative leg of the carbon; in any case this shielding destroys the effect.

(11.) If, instead of shielding the negative leg of the carbon, a mica screen is interposed between the negative leg and that side of the middle plate which faces it, then the current produced in a galvanometer connected between the positive terminal of the lamp and the middle plate is much reduced. Hardly any effect under the same circumstances is produced when the mica screen is interposed on that side of the metal plate which faces the positive leg of the carbon.

(12.) The position of the metal plate has a great influence on the magnitude of the current traversing a galvanometer connected between the metal plate and the positive terminal of the lamp. The current is greatest when the insulated metal plate is as near as possible to the base of the negative leg of the carbon, and greatest of all when it is formed into a cylinder which embraces without touching the base of the negative leg.

The current becomes very small when the insulated metal plate is removed to 4 or 5 inches from the negative leg, and becomes practically zero when the metal plate is at the end of a tube forming part of the bulb, which tube has a bend at right angles in it. Copious experiments have been made with metal plates in all kinds of positions.

(13.) The galvanometer current is greatly influenced by the surface of the metal plate, being greatly reduced when the surface of the plate is made small, or when the plate is set edgeways to the negative leg, so as to present a very small apparent surface when seen from the negative leg. In a lamp having the usual commercial vacuum, the effect is extremely small when the insulated metal plate is placed at a distance of 18 inches from the negative leg, but even then it is just sensible to a very sensitive galvanometer.

(14.) If a charged condenser has one plate connected to the insulated metal plate, and the other plate connected to any point of the circuit of the incandescent filament, this condenser is instantly discharged if the positively charged side of the condenser is connected to the insulated plate, and the negative side to the hot filament. If, however, the negative leg of the carbon horseshoe is shielded by a glass tube, this discharging power is much reduced, or altogether removed.

(15.) If the middle plate consists of a separate carbon loop, which can itself be made incandescent by a separate insulated battery, then, when this middle carbon is rendered incandescent and employed as the metal plate in the above experiment, the condenser is discharged when the negatively charged side of it is connected to the hot middle carbon, the positively charged side of it being in connexion with the principal carbon horseshoe.

(16.) If this last form of lamp is employed as in (4) the subsidiary carbon loop being used as a middle plate, and a galvanometer being connected between it and either the positive or negative main terminal of the lamp, then when the subsidiary carbon loop is cold, we get a current through the galvanometer only when it is in connexion with the positive main terminal of the lamp, but when the subsidiary carbon is made incandescent by a separate insulated battery, we get a current through the galvanometer when it is connected either to the positive *or* to the negative terminal of the lamp. In the first case the current through the galvanometer is a negative current, flowing from the middle carbon to the positive main terminal, and in the second case it is a negative current, from the negative main terminal to the middle subsidiary hot carbon.

(17.) If a lamp having a metal middle plate held between the legs of the carbon loop has a galvanometer connected between the negative main terminal of the lamp and this middle plate, we find that when the carbon is incandescent there is no sensible current flowing through the galvanometer. The vacuous space between the middle plate and the hot negative leg of the carbon possesses, however, a curious unilateral conductivity. If a single Clark cell is inserted in series with the galvanometer, we find that this cell can send a current deflecting the galvanometer when its negative pole is in connexion with the negative main terminal of the lamp, but if its positive pole is in connexion with the negative terminal of the lamp, then no current flows. The cell is thus able to force a current through the vacuous space when the direction of the cell is such as to cause negative electricity to flow across the vacuous space from the hot carbon to the cooler metal plate, but not in the reverse direction.

(18.) If a vacuum tube is constructed, having at each end horseshoe carbon filaments sealed into it, and which can each be made separately incandescent by an insulated battery, we find that such a vacuum tube, though requiring an electromotive force of many thousands of volts to force a current through it when the carbon loops are used as electrodes and are *cold*, will yet pass the current from a single Clark cell when the carbon loop which forms the negative electrode is rendered incandescent. It is thus found that a high vacuum terminated electrically by unequally heated carbon electrodes possesses an unilateral conductivity, and that electric discharge takes place freely through it under an electromotive force of a few volts when the *negative* electrode is made highly incandescent.

(19.) These experimental results above described led the writer to investigate, in the same manner, the electric arc between carbon poles taken in air. If an electric arc is formed, in the usual way, between carbon poles, and a third insulated carbon pole is allowed to dip into or touch the electric arc, or, better still, has the electric arc projected

2989

against it by a magnet, it is found that this third or insulated pole is brought down almost to the potential of the negative carbon of the arc, and that a galvanometer connected between the third insulated carbon and the negative carbon of the arc indicates no current, but that if joined up between the positive carbon and the middle carbon a strong current of about an ampère or so is found to be passing. If an electric bell or an incandescent lamp is joined up between the third carbon and the *negative* carbon of the arc, they do not work; but if the bell or the lamp is joined between the *positive* carbon of the arc and the third carbon, they are set in action by a strong current passing through them. These effects are produced, although the third carbon (which is best held at right angles to the other two forming the arc) is half or three quarters of an inch away from the positive and negative carbon, the sole condition being that the flame of the arc must touch or be projected by a magnet so as to touch this third carbon. We have, therefore, similar phenomena in the case of the arc and incandescence lamps.

(20.) When the electric arc is being projected against the third carbon, and has brought it down to the same potential, a galvanometer joined in between the two carbons shows no current; but this space between the negative carbon of the arc and the third carbon possesses a unilateral conductivity, and will pass the current from a small battery of secondary cells one way, but not the other. The secondary battery when joined in series with the galvanometer sends a current, if its negative pole is in connexion with the negative carbon of the arc, and its positive pole, through the galvanometer, with the third carbon; but if the secondary battery is reversed in position it sends no current. Negative electricity can pass along the flame-like projection of the arc *from* the hot negative carbon *to* the cooler third carbon, but not in an opposite direction.

(21.) If the arc is projected by means of a magnet for a long time against the third insulated carbon, it *craters* it out in the same fashion as the crater of the positive carbon, and the tip of this third carbon, where it has received the flame-like blast of the arc, is converted into graphite.

The same effects are observed if an iron rod is used as a third pole, and in this case the end is converted into *steel*, and rendered so hard as to be scarcely touched by the file when it has been quenched in water.

In seeking for an hypothesis to connect together these observed facts, the one which suggests itself as most in accordance with the facts is as follows:—

In the case of a carbon incandescence lamp when at vivid incandescence, carbon particles are being projected from all parts of the filament, but chiefly from the negative half of the loop. These carbon

molecules carry *negative* charges of electricity, and when they impinge upon a metal plate placed in the vacuum they can discharge themselves if this plate is positively electrified, either by being in metallic connexion with the positive electrode of the lamp or with a separate positively charged body. When the plate is simply insulated the stream of negatively charged carbon molecules brings down this insulated plate to the potential of the base of the negative leg, or to the potential of that part of the carbon conductor from which it is receiving projected molecules. These carbon molecules projected from an incandescent conductor can carry negative charges, but either cannot be positively charged, or else lose a positive charge almost instantly when projected off from the conductor.

In the case of the electric arc we must suppose that the negative carbon is projecting off a torrent of negatively electrified carbon molecules, and these, impinging against the positive carbon, wear out a crater in it by a sand-blast-like action.

The higher temperature of the positive carbon in a continuous current arc is thus explained as due to the impact of the carbon molecules projected from the negative carbon.

If the electric arc is diverted against a third insulated lateral carbon, the carbon blast from the negative carbon wears out a crater in it and brings it down to the same potential as itself. The actions going on in an electric arc may be considered to be somewhat as follows:—When the carbons are first put together, the resistance at the point of contact renders the extremities incandescent. When thus incandescent and separated, the electrification of each carbon is sufficient to begin the projection of molecules from both positive and negative carbons, probably most largely from the latter. The impact of the molecular stream from the negative pole raises the temperature of the positive carbon, and this again by radiation raises the temperature of the negative carbon end. The electromotive force is thus able to keep up a projection of negatively charged carbon molecules from the end of the negative carbon, which molecules are loosened from the mass by heat, and then move away by electric repulsion from the surface in virtue of the electric charge which they retain. It would seem as if a hot carbon molecule cannot retain a positive charge, and hence the potential difference between a third insulated carbon and the positive carbon of the arc is nearly the same as the potential difference of the positive and negative carbons of the arc. The rise of potential along the arc takes place very suddenly just in the neighbourhood of the crater of the positive carbon.

It has often been suggested that the electric arc contains a counter-electromotive force. It is questionable whether such experiments as those of Edlund ('Phil. Mag.,' vol. 36, 1868, p. 352) are entirely conclusive on this point.

2991

3121

It has been shown by other experimenters* that for arcs of varying length, but the same current, beyond a certain small initial length, the potential difference necessary to maintain the arc is proportional to the length of the arc plus a constant. This might thus be interpreted to mean that a certain proportion of the working electromotive force of the arc was employed in detaching the carbon molecules from the mass of the poles, and that the excess alone is represented by the current produced in an arc of definite length.

In the case of the incandescence lamps the hypothesis of the projection of negatively charged carbon molecules from the incandescent conductor, to which the name of *molecular electrocection* may be given, will suffice to explain all the various different effects produced by varying the surface, position, and distance of the metal plate against which they impinge, and also the nullifying effect of shielding this plate from the negative leg of the carbon.

That this molecular discharge goes on chiefly from the negative leg is additionally proved by the greater erosion which takes place in the deposit of carbon on the negative leg when the carbon is uniform and traversed by a continuous current.

The hypothesis that a carbon molecule detached from an incandescent carbon surface in a high vacuum can only convey away a negative charge, reconciles also the above described observed effects in which a negative discharge can be made *out* of a hot surface of carbon more easily than a positive discharge. When an electromotive force is applied to two metallic terminals or electrodes sealed into a good vacuum, it is well known that a certain initial electromotive force has to be applied before any electric current begins to flow through the gas at all. It seems conclusively proved by Mr. Crookes's researches that the nature of an electric discharge through a high vacuum consists in a torrent of electrified particles proceeding from the negative electrode. If this is the case the initial electromotive force required to begin a discharge through such rarefied gas would naturally be reduced by heating the negative electrode, so as to favour and assist the detachment of the charged molecules of that electrode. The effect of heating the negative electrode in facilitating discharge through vacuous spaces has previously been described by W. Hittorf ('Annalen der Physik und Chemie,' vol. 21, 1884, p. 90—139), and it is abundantly confirmed by the above experiments. We may say that a vacuous space bounded by two electrodes—one incandescent, and the other cold—possesses a unilateral conductivity for electric discharge when these electrodes are within a distance of the mean free path of projection of the mole-

* See Professors Ayrton and Perry, 'Proceedings of the Physical Society,' vol. 5, p. 201.

2992

3123

cules which the impressed electromotive force can detach and send off from the hot negative electrode.

This unilateral conductivity of vacuous spaces having unequally heated electrodes has been examined by MM. Elster and Geitel (see 'Wiedemann's Annalen,' vol. 38, 1889, p. 40), and also by Goldstein ('Wied. Ann.,' vol. 24, 1885, p. 83), who in experiments of various kinds have demonstrated that when an electric discharge across a vacuous space takes place from a carbon conductor to another electrode, the discharge takes place at lower electromotive force when the carbon conductor is the negative electrode and is rendered incandescent.

[fol. 2995] DEFENDANT'S EXHIBIT J-1

Proceedings of Royal Institution of Great Britain, 1890-1892.

Weekly Evening Meeting, Friday, February 14, 1890. William Crookes, Esq., F.R.S. Vice President, in the Chair Professor J. A. Fleming, M.A. D.Sc. M.R.I. Problems in the Physics of an Electric Lamp

More than eighty years ago Sir Humphry Davy provided the terminal wires of his great battery of 2000 pairs of plates with rods of carbon, and, bringing their extremities in contact, obtained for the first time, a brilliant display of the electric arc.[1] The years that have fled away since that time have seen all the marvelous developments of electro magnetic engineering, have placed in our possession the electric glow-lamp, and brought the art of electrical illumination to a condition in which it progresses each year with giant strides. In addition to the importance attaching to their ever-increasing industrial use, there are many questions of purely scientific interest which present themselves to our minds when we proceed to examine the actions [fol. 2996] that take place when a carbon conductor is rendered incandescent in a high vacuum, or when an electric arc is formed between two carbon poles. It is to a very few of these physical problems that I desire to direct your attention to-night, but more especially to one which is particularly interesting from the bearing which it has on the general nature of electric discharge.

We know as a very familiar fact that if we attempt to raise the temperature of a carbon conductor enclosed in a vacuum beyond a certain limit, not far removed from the melting point of platinum, the carbon begins to volatilise

[1] Sir Humphry Davy laid a request before the managers of the Royal Institution on July 11th, 1808, that they would set on foot a subscription for the purchase of a large galvanic battery. The result of this suggestion was that a galvanic battery of 2,000 pairs of copper and zinc plates were set up in the Royal Institution, and one of the earliest experiments performed with it was the production of the electric arc between carbon poles, on a large scale. It is probable, however, that Davy had produced the light on a small scale some six years before and, according to Quetelet, Curtet observed the arc between carbon points in 1802. See Dr. Paris' "Life of Sir H. Davy."

with great rapidity. If an electric glow-lamp has passed through its carbon more than a certain strength of current, the glass bulb speedily becomes darkened by a deposit of this volatilised carbon condensed upon it; and experience shows us that we cannot raise the temperature of that carbon beyond a definite point without causing this waste of the conductor to become very rapid. In the highly rarefied atmosphere within the bulb of a glow lamp, the carbon, when at its normal incandescence, must be considered to be projecting off molecules of carbon in all directions, partly in virtue of purely thermal actions, but probably also in consequence of certain electrical effects to be presently discussed. This scattering of the material of the carbon conductor takes place with disadvantageous rapidity from an industrial point of view at and beyond a certain temperature,[2] but it exists as well at much lower temperatures than that which is found to determine the practical limit of durability. A curious appearance is found in many incandescent lamps which have been "over-run," which shows us that this projection of carbon molecules from the hot conductor is not, perhaps, best described by calling it a vaporisation of its substance, but that the surface molecules are shot off in straight lines, and that they reach the glass envelope without being hindered to any great extent by the molecules of the residual air.

If an electric current is passed through an otherwise uniform carbon conductor, which possesses at any one place a specific resistance higher than that of the remaining portion, the current, in accordance with a well-known law, there develops a higher temperature, and the molecular scattering at that spot may in consequence be greatly exaggerated. It may be that the detrition of the conductor at that locality will be so great as to cut it through after a very short time. When the carbon has the form of a simple horseshoe loop, and when this molecular scattering takes place from some point in the middle of one branch, the molecular projection makes itself evident by producing a

[2] When the rate of expenditure of energy in the carbon conductor is raised until it reaches a value of about 500 watts, or 360 foot pounds per second per square inch of radiative surface, a limit of useful temperature has been reached for economical working, under the usual present conditions of steam-engine-driven dynamos and modern glow-lamps.

"molecular shadow" of the other leg upon the interior of the glass. I will project upon the screen an image of the carbon horseshoe loop taken from an old glow-lamp, and you will be able to see that the filament has been cut through at one place. At that position some minute congenital defect caused the carbon to have a higher resistance, the temperature at that point when it was in use became ex- [fol. 2997] cessive, and an intensified molecular scattering took place from that locality. On examining the glass bulb from which it was taken, we find that the glass has been everywhere darkened by a deposit of the scattered carbon except along one narrow line (*see* Fig. 1), and that line is in the plane of the carbon loop and on the side opposite to the point of rupture of the filament.[3]

I may illustrate to you by a very simple experiment the way in which that "shadow" has been formed. Here is a ∩-shaped rod: this shall represent the carbon conductor in the lamp: this sheet of cardboard placed behind it, the side of the glass receiver. I have affixed a little spray-producer to one side of the loop, and from that point blow out a spray of inky water. Consider the ink spray to represent the carbon atoms shot off from the overheated spot. We see that the cardboard is bespattered on all points except along one line where it is sheltered by the opposite side of the loop. We have thus produced a "spray shadow" on the board (Fig. 2). The existence of these molecular shadows in incandescent lamps leads us therefore to recognise that the carbon atoms must be shot off in straight lines, or else obviously no such sharp shadow could thus be formed. This phenomenon confirms in a very beautiful manner the deductions of the Kinetic theory of gases. I may remind you that at the ordinary temperature and pressure the mean free path of a molecule of air is deducted to be about four one-millionths of an inch. This is the average distance which such a gaseous molecule moves over before meeting with a collision against a neighbour which changes [fol. 2998] the direction of its path. Let the air be rarefied, as in these bulbs, to something like a millionth of the ordinary atmospheric pressure, and the mean free path is increased to several inches. The space within the bulb though from one point of view densely populated with

[3] The writer desires to express his indebtedness to the Editor of the "Electrician" for the loan of the blocks illustrating this abstract.

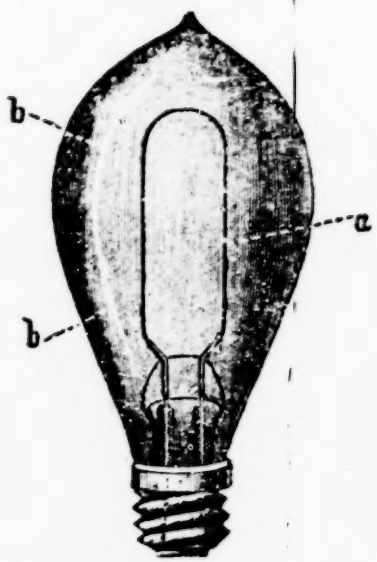

FIG. 1. Glow-lamp, having the glass bulb blackened by deposit of carbon, showing the molecular scattering which has taken place from the point *a* on the filament, and the shadow in line of no deposit produced at *b*.

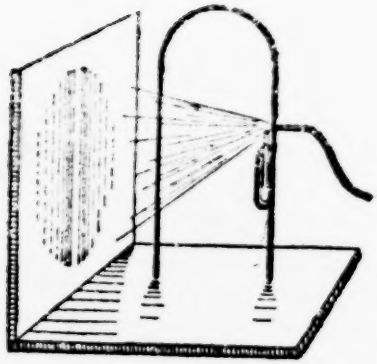

FIG. 2. "Spray shadow" of a rod thrown on cardboard screen to illustrate formation of molecular shadow in glow lamps.

molecules of residual air—is yet, as a fact, in such a condition of rarefaction that a carbon molecule projected from the conductor can move over a distance of three or four inches on an average without meeting with interference by collision with another molecule, and the facts revealed to us by these shadows show that this must be the case. I have also at hand some Edison lamps in which these "molecular shadows" are finely shown, but in these cases the deposit on the interior of the bulb is not carbon but copper, because the molecular scattering has here taken place by excessive temperature developed at the copper clamps by which the carbon filament is attached to the platinum wires. The theory, however, is the same. The deposit of copper shows a fine green colour by transmitted light in the thinner portions. One curious lamp also before me had by an accident an aluminium plate volatilised within the bulb. The glass receiver has in consequence been covered with a mirror-like deposit of aluminium, which on the thinner portions shows a fine blue colour by transmitted light, and a silvery lustre by reflected light. This lamp also shows a fine "molecular shadow."

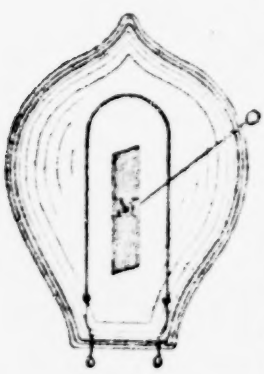

FIG. 3. Glow-lamp having insulated metal middle plate M sealed into bulb to exhibit Edison effect.

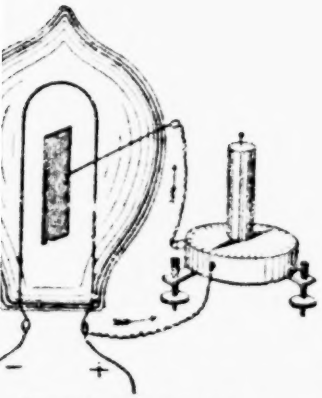
These facts prepare us to accept the view that when a glow-lamp is in operation the highly rarefied residual air in the interior of the bulb is being traversed in all directions by multitudinous carbon atoms projected off from the incandescent carbon conductor. I now wish to pass in review before you some facts which indicate that these carbon atoms carry with them electric charges, and that they are charged, if at all, with *negative electricity*. I may preface all by saying that much of what I have to show you will be seen to be closely related to the phenomena studied by Mr. Crookes in his splendid and classical researches on radiant matter. Our starting-point for this purpose is a discovery made by Mr. Edison in 1884, and which received careful examination at the hands of Mr. Preece in the following year,[1] and by myself more recently. Here is the initial experiment. A glow-lamp having the usual horse-shaped carbon (*see* Fig. 3) has a metal plate held on a platinum shoe wire sealed through the glass bulb. This plate is so fixed out it stands up between the two sides of the carbon arch without touching either of them. We shall illuminate the lamp by continuous current of electricity, and for brevity's sake speak of that half of the loop of carbon on the side by which the current enters it as the positive leg, [fol. 2999] and the other half of the loop as the negative leg. The diagram in Fig. 4 shows the position of the plate with respect to the carbon loop. There is a distance of half an inch, or in some cases many inches, between either leg of the carbon and this middle plate. Setting the lamp in action, I connect a sensitive galvanometer between the middle plate and the *negative terminal* of the lamp, and you see that there is no currents passing through the instrument. If, however, I connect the terminals of my galvanometer to the middle plate and to the *positive electrode* of the lamp, we find a current of some milliamperes is passing through it. The diagrams in Fig. 5 show the mode of connection of the galvanometer in the two cases. This effect, which is often spoken of as the "Edison effect," clearly indicates that an insulated plate so placed in the vacuum of a lamp in action is brought down to the same potential or electrical

[1] Mr. Preece's interesting paper on this subject is published in the "Proceedings" of the Royal Society for 1885, p. 219. See also "The Electrician," April 4th, 1885, p. 426.



Sensitive galvanometer connected

as the negative electrode of the carbon loop. On
ning the direction of the current through the galva-
er we find that it is equivalent to a flow of negative
icity taking place through it *from* the middle plate *to*
sitive electrode of the lamp. A consideration of this
hows us that there must be some way by which nega-
lectricity gets across the vacuous space from the nega-
g of the carbon to the metal plate, whilst at the same
negative charge cannot pass from the metal plate
to the positive leg. Before I pass away from this
experiment, I should like to call your attention to a
s effect at the moment when the lamp is extinguished.
ecting the galvanometer as at first, between the middle
nd the negative electrode of the lamp, we notice that
h made highly sensitive the galvanometer indicates
rent flowing through it whilst the lamp is in action.
ing off the current from the lamp produces, as you
violent kick or deflection of the galvanometer, indi-
a sudden rush of current through it.

ndeavoring to ascertain further facts about this effect
the experiments which early suggested itself was one
1000] directed to determine the relative effects of
nt portions of the carbon conductor. Here is a lamp
ig. 6) in which one leg of the carbon horseshoe has
nclosed in a glass tube of the size of a quill, which
s one-half of the carbon. The bulb contains, as be-
n insulated middle plate. If we pass the actuating
t through this lamp in such a direction that the
d or sheathed leg is the *positive* leg, we find the

effect existing as before. A galvanometer connected between the plate and positive terminal of the lamp yields a strong current, whilst if connected between the negative terminal and the middle plate there is no current at all. Let us, however, reverse the current through the lamp so that the shielded or enclosed leg is now the negative one, and the galvanometer is able to detect no current, whether connected in one way or the other. We establish, therefore, the conclusion that it is the negative leg of the carbon loop which is the active agent in the production of this "Edison effect," and that if it is enclosed in a tube of either glass or metal, no current is found flowing in a galvanometer connected between the positive terminal of the lamp and this middle collecting plate.

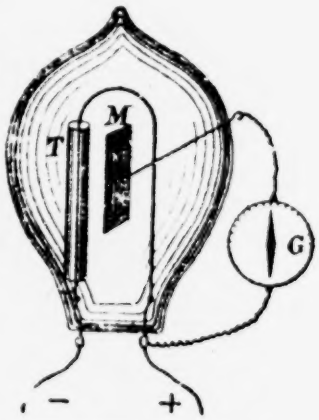

FIG. 6.—Glow-lamp having negative leg of carbon enclosed in glass tube *T*, the "Edison effect" thereby being annulled or greatly diminished.

Another experiment which confirms this view is as follows:—This lamp (see Fig. 7) has a middle plate, which is provided with a little mica flap or shutter on one side of it. When the lamp is held upright the mica shield falls over and covers one side of the plate, but when it is held in a horizontal position the mica shield falls away from the front of the plate and exposes it. Using this lamp as before we find that when the positive leg of the carbon loop is opposite to the shielded face of the plate, we get the "Edison effect" as before in any position of the lamp. Reversing the lamp current and making that same leg the *negative* one, we find that when the lamp is so held the metal plate is shielded by the interposition of the mica, and the galvanometer current is very much less than when the shield is shaken on one side and the plate exposed fully to the negative leg.

At this stage it will perhaps be most convenient to outline briefly the beginnings of a theory proposed to reconcile these facts, and leave you to judge how far the subsequent experiments confirm this hypothesis. The theory very briefly is as follows: From all parts of the incandescent carbon loop, but chiefly from the negative leg, carbon molecules are being projected which carry with them, or are charged with, negative electricity. I will in a few moments make a suggestion to you which may point to a possible

hypothesis on the manner in which the molecules acquire this negative charge. Supposing this, however, to be the case, and that the bulb is filled with these negatively-charged molecules, what would be the result of introducing [fol. 3001] into their midst a conductor such as this middle metal plate which is charged positively? Obviously, they would all be attracted to it and discharge against it. Suppose the positive charge of this conductor to be continually renewed, and the negatively-charged molecules continually supplied, which conditions can be obtained by connecting the middle plate to the positive electrode of the lamp, the obvious result will be to produce a current of electricity flowing through the wire or galvanometer, by means of which this middle plate is connected to the positive electrode of the lamp. If, however, the middle plate is connected to the negative electrode of the lamp, the negatively charged molecules can give up no charge to it, and produce no current in the interpolated galvanometer. We see that on this assumption the effect must necessarily be diminished by any arrangement which prevents these negatively charged molecules from being shot off the negative leg or from striking against the middle plate. Another obvious corollary from this theory is that the "Edison effect" should be annihilated if there a metal collecting plate is placed at a distance from the negative leg much greater than the mean free path of the molecules.

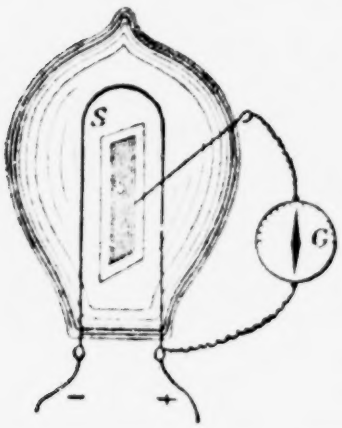

FIG. 7.—Glow-lamp having mica shield S interposable between middle plate M and negative leg of carbon, thereby diminishing the "Edison effect."

Here are some experiments which confirm this deduction. In this bulb (Fig. 8) the metal collecting plate, which is to be con-

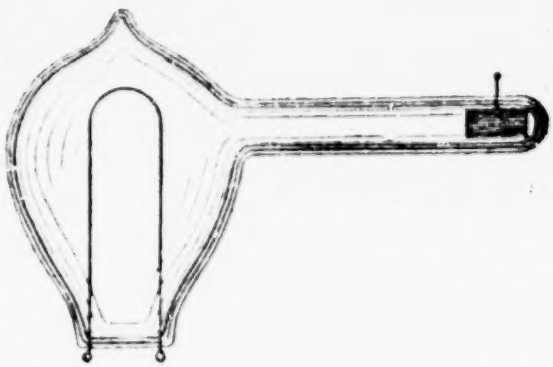

FIG. 8.—Collecting plate placed at end of a tube [illegible] length, opening out of the bulb [illegible]

nected through the galvanometer with the positive terminal of the lamp, is placed at the end of a long tube opening out of and forming part of the bulb. We find the "Edison effect" is entirely absent, and that the galvanometer current is zero. We have, as it were, placed our target at such a distance that the longest range molecular bullets cannot hit it, or, at least, but very very few of them do so. Here again is a lamp in which the plate is placed at the extremity of a tube opening out of the bulb, but bent at right angles (Fig. 9). We find in this case, as first discovered by Mr. Preece, that there is no "Edison effect." Our molecular marksman cannot shoot round a corner. None of the negatively-charged molecules can reach the plate, although that plate is placed at a distance not greater than [fol. 3002] would suffice to produce the effect if the bend were straightened out. Following out our hypothesis into its consequences would lead us to conclude that the material of which the plate is made is without influence on the result, and this is found to be the case. Many of the foregoing facts were established by Mr. Preece as far back as 1885, and I have myself abundantly confirmed his results.

We should expect also to find that the larger we make our plate, and the nearer we bring it to the negative leg of the carbon, the greater will be the current produced in a circuit connecting this plate to the positive terminal of the lamp. I have before me a lamp with a large plate placed very near the negative leg of the carbon of a lamp, and we find that we can collect enough current from these molecular charges to work a telegraph relay and ring an electric bell. The current which is now working this relay is made up of the charges collected by the plate from the negatively-charged carbon molecules which are projected against it from the negative leg, across the highly perfect vacuum. I have tried experiments with lamps in which the collecting plate is placed in all kinds of positions, and has various forms, some of which are here, and are represented in the diagrams before you; but the result may all be summed up by saying that the greatest effects are pro-

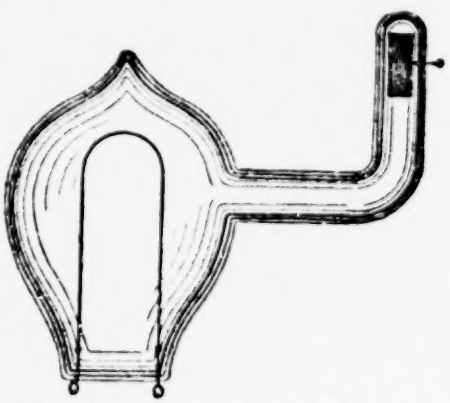

FIG. 9.—Collecting plate placed at end of an elbow tube opening out of the bulb.

duced when the collecting plate is as near as possible to the base of the negative end of the loops, and, as far as possible, encloses, without touching, the carbon conductor. Time will not permit me to make more than a passing reference to the fact that the magnitude of the current flowing through the galvanometer when connected between the middle plate and the positive terminal of the lamp often "jumps" from a low to a high value, or *vice versâ*, in a remarkable manner, and that this sudden change in the current can be produced by bringing strong magnets near the outside of the bulb.

Let us now follow out into some other consequences this hypothesis that the interior of the bulb of a glow-lamp when in action is populated by flying crowds of carbon atoms all carrying a negative charge of electricity. Suppose we connect our middle collecting plate with some external reservoir of electric energy, such as a Leyden jar, or with a condenser equivalent in capacity to many hundreds of Leyden jars, and let the side of the condenser which is charged positively be first placed in connection through a galvanometer with the middle plate (see Fig. 10), whilst the negative side is placed in connection with the earth. Here is a condenser of two microfarads capacity so charged and connected. Note what happens when I complete the circuit and illuminate the lamp by passing the [fol. 3003] current through its filament. The condenser is at once discharged. If, however, we repeat the same experiment with the sole difference that the negatively charged side of the condenser is in connection with the middle plate then there is no discharge. The experimental results may be regarded from another point of view. In order that the condenser may be discharged as in the first case, it is essential that the negatively charged side of the condenser shall be in connection with some part of the circuit of the incandescent carbon loop. This experiment with the condenser discharged by the lamp may be then looked upon as an arrangement in which the plates of a charged condenser are connected respectively to an incandescent carbon loop and to a cool metal plate, both being enclosed in a highly vacuous space, and it appears that when the incandescent conductor is the negative electrode of this arrangement the discharge takes place, but not when the cooler metal plate is the negative electrode of the charged

condenser. The negative charge of the condenser can be carried across the vacuous space from the hot carbon to the colder metal plate, but not in the reverse direction.

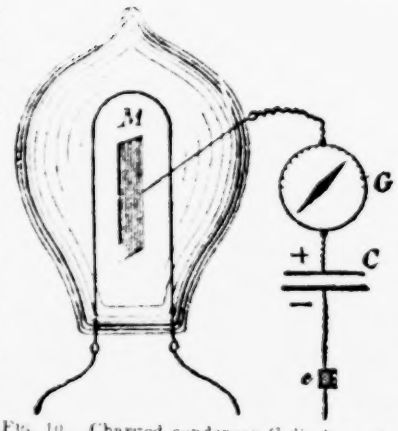

Fig. 10. Charged condenser C discharged by middle plate M, when the positively charged side of condenser is in connection with the plate and other side to earth e.

This experimental result led me to examine the condition of the vacuous space between the middle metal plate and the negative leg of the carbon loop in the case of the lamp employed in our first experiment. Let us return for a moment to that lamp. I join galvanometer between the middle plate and the negative terminal of the lamp, and find, as before, no indication of a current. The metal plate and the negative terminal of the lamp are at the same electrical potential. In the circuit of the galvanometer we will insert a single galvanic cell having an electromotive force of rather over one volt. In the first place let that cell be so inserted that its negative pole is in connection with the middle plate, and its positive pole in connection through the galvanometer with the negative terminal of the lamp (see Fig. 11). Regarding the circuit of that cell alone, we find that it consists of the cell itself, the galvanometer wire, and that half-inch of highly vacuous space between the hot carbon conductor and the middle plate. In that circuit the cell cannot send any sensible current at all, as it is at the present moment connected up. But if we reverse the direction of the cell so that its positive pole is in connection with the middle plate, the galvanometer at once gives indications of a very sensible current. This highly vacuous space, lying between the middle metal plate on the one hand, and the incandescent carbon on the other, possesses a kind of unilateral conductivety, in that it will allow the current from [fol. 3004] a single galvanic cell to pass one way but not the other. It is a very old and familiar fact that in order to send a current from a battery through a highly rarefied gas by means of metal electrodes, the electromotive force of the battery must exceed a certain value. Here, however, we have indication that if the negative electrode by which that current seeks to enter the vacuous space is made incan-

descent the current will pass at a very much lower electromotive force than if the electrode is not so heated.

A little consideration of the foregoing experiments led to the conclusion that in the original experiment, as devised by Mr. Edison, if we could by any means render the middle plate very hot, we should get a current flowing through a galvanometer when it is connected between the middle plate and the negative electrode of the carbon. This experiment can be tried in the manner now to be shown. Here is a bulb (Fig. 12) having in it two carbon loops; one

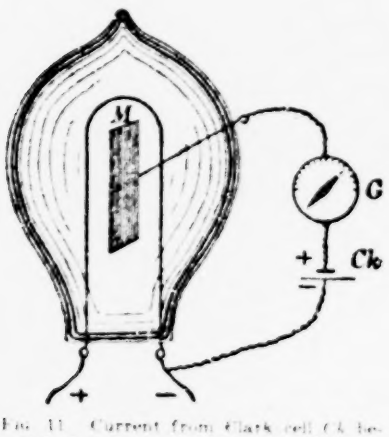

FIG. 11. Current from Clark cell *Cb* being sent across vacuous space between negative leg of carbon and middle plate *M*. Positive pole of cell in connection with plate *M* through galvanometer *G*.

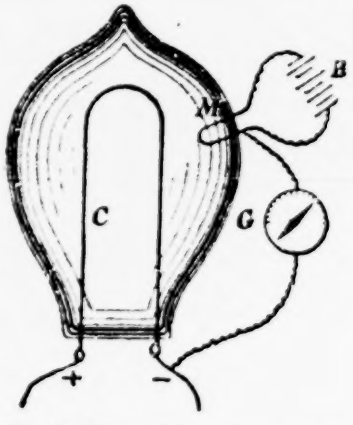

FIG. 12. Experiment showing that when the "middle plate" is a carbon loop rendered incandescent by insulated battery *B*, a current of negative electricity flows from *M* to the positive leg of main carbon *C* across the vacuum.

of these is of ordinary size, and will be rendered incandescent by the current from the mains. The other loop is very small, and will be heated by a well-insulated secondary battery. This smaller incandescent loop shall be employed just as if it were a middle metal plate. It is, in fact, simply an incandescent middle conductor. On repeating the typical experiment with this arrangement, we find that the galvanometer indicates a current when connected between the middle loop and either the positive *or* the negative terminal of the main carbon. I have little doubt but that if we could render the platinum plate in our first used lamp incandescent by concentrating on it from outside a powerful beam of radiant heat we should get the same result.

A similar set of results can be arrived at by experiments

with a bulb constructed like an ordinary vacuum tube, and having small carbon loops at each end instead of the usual platinum or aluminium wires. Such a tube is now before you (*see* Fig. 13), and will not allow the current from a few cells of a secondary battery to pass through it when the car- [fol. 3005] bon loops are cold. If, however, by means of well insulated secondary batteries we render both of the carbon loop electrodes highly incandescent, a single cell of a battery is sufficient to pass a very considerable current across that vacuous space provided the resistance of the rest of the circuit is not large. We may embrace the foregoing facts by saying that if the electrodes, but especially the negative electrode, which form the means of ingress and egress of a current into a vacuous space are capable of being rendered highly incandescent, and if at that high temperature they are made to differ in electrical potential by the application of a very small electromotive force, we may get under these circumstances a very sensible current through the rarefied gas. If the electrodes are cold a very much higher electromotive force will be necessary to begin the discharge or current through the space. These facts have been made the subject of elaborate investigation by Hittorf and Goldstein, and more recently by Elster and Geitel. It is to Hittorf that I believe we are indebted for the discovery of the fact that by heating the negative elec

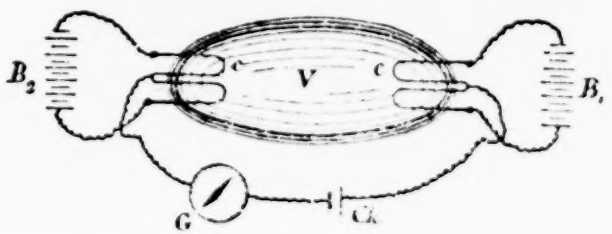

Fig. 13.—Vacuum tube having carbon loop electrodes, cc, at each end rendered incandescent by insulated batteries B_2 B_1, showing current from Clark cell, Cx, passing through the high vacuum when the electrodes are incandescent.

trode we greatly reduce the apparent resistance of a vacuum.

Permit me now to pave the way by some other experiments for a little more detailed outline of the manner in which I shall venture to suggest these negative molecular

charges are bestowed. This is really the important matter to examine. In seeking for some probable explanation of the manner in which these wandering molecules of carbon in the glow-lamp bulb obtain their negative charges, I fall back for assistance upon some facts discovered by the late Prof. Guthrie. He showed some years ago new experiments on the relative powers of incandescent bodies for retaining positive and negative charges. One of the facts he brought forward[1] was that a bright red-hot iron ball, well insulated, could be charged negatively, but could not retain for an instant a positive charge. He showed this fact in a way which it is very easy to repeat as a lecture experiment. Here is a gold-leaf electroscope, to which we will impart a positive charge of electricity, and project the image of its divergent leaves on the screen. A poker, the tip of which has been made brightly red-hot, is placed so that its incandescent end is about an inch from the knob of the electroscope. No discharge takes place. Discharging the elec- [fol. 3006] troscope with my finger, I give it a small charge of negative electricity, and replace the poker in the same position. The gold leaves instantly collapse. Bear in mind that the extremity of the poker, when brought in contiguity to the knob of the charged electroscope, becomes charged by induction with a charge of the opposite sign to that of the charge of the electroscope, and you will at once see that this experiment confirms Prof. Guthrie's statement, for the negatively-charged electroscope induces a positive charge on the incandescent iron, and this charge cannot be retained. If the induced charge on the poker is a negative charge, it is retained, and hence the positively-charged electroscope is not discharged, but the negatively-charged electroscope at once loses its charge. Pass in imagination from iron balls to carbon molecules. We may ask whether it is a legitimate assumption to suppose the same fact to hold good for them, and that a hot carbon molecule or small carbon mass just detached from an incandescent surface behaves in the same way and has a greater grip for nega-

[1] "On a New Relation between Electricity and Heat," Phil. Mag. vol. xlv. p. 308. 1873.

tive than for positive charge? If this can possibly be assumed, we can complete our hypothesis as follows:—Consider a carbon molecule or small congerie of molecules just set free by the high temperature from the negative leg of the incandescent carbon horseshoe. This small carbon mass finds itself in the electrostatic field between the branches of the incandescent carbon conductor (*see* Fig. 14). It is acted upon inductively, and if it behaves like the hot iron ball in Prof. Guthrie's experiment it loses its positive charge. The molecule then being charged negatively is repelled along the lines of electric force against the positive leg. The forces moving it are electric forces, and the repetition of this action would cause a torrent of negatively-charged molecules to pour across from the negative to the positive side of the carbon horseshoe. If we place a metal plate in their path, which is in conducting connection with the positive electrode of the lamp carbon, the negatively-charged molecules will discharge themselves against it. A plate so placed may catch more or less of this stream of charged molecules which pour across between the heels of the carbon loop. There are many extraordinary facts, which as yet I have been able only imperfectly to explore, which relate to the sudden changes in the direction of the principal stream of these charged molecules, and to their guidance under the influence of magnetic forces. The above rough sketch of a theory must be taken for no more than it is worth, viz. as a working hypothesis to suggest further experiments.

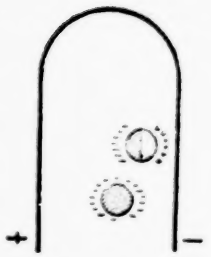

Fig. 14.—Rough diagram illustrating a theory of the manner in which projected carbon molecules may acquire a negative charge.

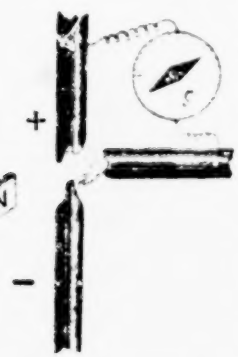
These experiments with incandescence lamps have prepared the way for me to exhibit to you some curious facts with respect to the electric arc, and which are analogous to those which we have passed in review. If a good electric arc is formed in the usual way, and if a third insulated carbon held at right angles to the other two is [fol. 3007] placed so that its tip just dips into the arc (*see* Fig. 15), we can show a similar series of experiments. It is rather more under control if we cause the arc to be

ed against the third carbon by means of a magnet. now formed on the screen an image of the carbon nd the arc between them, in the usual way. Placing et at the back of the arc, I cause the flame of the be deflected laterally and to blow against a third d carbon held in it. There are three insulated wires d respectively to the positive and to the negative of the arc, and to the third or insulated carbon, of which dips into the flame of the arc projected magnet. On starting the arc this third carbon is y brought down to the same electrical potential as ative carbon of the arc, and if I connect this gal- ter in between the negative carbon and the third lated carbon I get, as you see, no indication of a Let me, however, change the connections and he circuit of my galvanometer in between the posi- bon of the arc and the middle carbon, and we find evidence, by the violent impulse given to the galvanometer, that there is a strong current flowing through it. The direction of this current is equivalent to a flow of negative electricity from the middle carbon through the galvanometer to the positive carbon of the arc. We have here then the "Edison effect" repeated with the electric arc. So strong is the current flowing in a circuit connecting the middle carbon with the positive carbon that I can, as you see, ring an electric bell and light a small incandescent lamp



lectric arc projected by gainst a third carbon, and a strong electric current rough a galvanometer G, between the positive and carbon.

ese electric-current detectors are placed in con- with the positive and middle carbons.

o find that the flame-like projection of the arc be- negative carbon possesses a unilateral conductiv- in this small secondary battery of fifteen cells in th the galvanometer, and connect the two between le carbon and the negative carbon of the arc. Just analogous experiment with the incandescent lamp, e can send negative electricity along the flame of ne way but not the other. The secondary battery

causes the galvanometer to indicate a current flowing through it when its negative pole is in connection with the negative carbon of the arc (*see* Fig 16), but not when its positive pole is in connection with the negative carbon. On examining the third or middle carbon after it has been employed in this way for some time, we find that its extremity is cratered out and converted into graphite, just as if it had been employed as the positive carbon in forming an electric arc. Time forbids me to indulge in any but the briefest remarks on these experiments; but one suggestion may be made, and that is that they seem to indicate that the chief movement of carbon molecules in the electric arc is *from* the [fol. 3008] negative *to* the positive carbon. The idea suggests itself that, after all, the cratering out of the positive carbon of the arc may be due to a sand-blast-like action of this torrent of negatively-charged molecules which are projected from the negative carbon. If we employ a soft iron rod as our lateral pole, we find that, after enduring for some time the projection of the arc against it, it is converted at the extremity into *steel*.

Into the fuller discusston as to the molecular actions going on in the arc, the source and nature of that which has been called the counter-electromotive force of the arc, and the causes contributing to produce unsteadiness and hissing in the arc, I fear that I shall not be able to enter, but will content myself with the exhibition of one last experiment, which will show you that a high vacuum, or, indeed, any vacuum, is not necessary for the production of the "Edison effect." Here is a carbon horseshoe-shaped conductor, not enclosed in any receiver (see Fig. 17). Close to the negative leg or branch, yet not touching it, we have adjusted a little metal plate. The sensitive galvanometer is connected between this metal plate and the base of the other or positive leg of this carbon arch. On sending a current through the carbon sufficient to

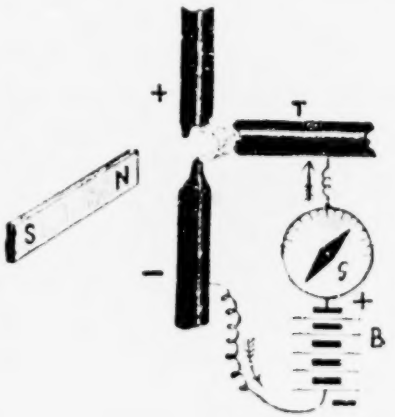


Fig. 16. Galvanometer *G* and battery *B* inserted in series between negative carbon of electric arc and a third carbon to show unilateral conductivity of the arc between the negative and third carbons.

bring it to bright incandescence, the galvanometer gives indications of a current flowing through it, and as long as the carbon endures, which is not, however, for many seconds, there is a current of electricity through it equivalent to a flow of negative electricity from the plate through the galvanometer to the positive electrode of the carbon. The interposition of a thin sheet of mica between the metal plate and the negative leg of the carbon loop entirely destroys the galvanometer current.[6]

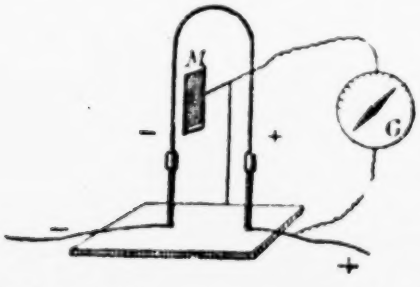

FIG. 17.—Edison effect" experiment shown with carbon in open air

These experiments and brief expositions cover a very small portion of the ground which is properly included within the limits of my subject. Such fragments of it as we have been able to explore tonight will have made it clear that it is a region abounding in interesting facts and problems in molecular physics. The glow-lamp and the electric are have revolutionized our methods of artificial lighting, but they present themselves also as subjects of scientific study, by no means yet exhausted of all that they have to teach.

[6] This last experiment is due to my assistant, Mr. A. H. Bate. [J. A. F.]

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE

No. 614.—Vol. XXIV. FRIDAY, FEBRUARY 21, 1890. Price Fourpence.

NOTES.

Mr. Swinburne's Paper on "The Theory of Armature Reactions in Dynamos and Motors," read before the Institution of Electrical Engineers on the 13th inst., will be discussed conjointly with Mr. Esson's communication on "Some Points in Dynamo and Motor Design," read last night.

The simplicity introduced into dynamo and motor design by looking at the subject from the magnetic point of view first suggested by Hopkinson and Kapp has received considerable support in Mr. Swinburne's valuable Paper. The effect of the distortion of the lines of magnetic force is still further brought out by the use of the term magnetic potential. [illegible] can thus be considered in parts just as [illegible] by which the electric potential and resistance [illegible]. The most serious case of magnetic leakage is [illegible]. There is however no justification for [illegible] of magnetic current at [illegible].

The reactions of the armature on the field magnets [illegible] the position of the brushes [illegible] which the [illegible] the weakening effect [illegible] the pole pieces and its strengthening effect [illegible] are simply and clearly [illegible]. The greater amount of sparking [illegible] of single magnet dynamos [illegible].

Mr. Swinburne is probably right in considering that [illegible] in connection with reducing the distortion [illegible] to avoid sparking at the brushes, and [illegible] of the commutator to [illegible] the magnetic leakage [illegible] Mr. Swinburne's [illegible].

In connection with the subject of magnetic potential, we may remind our readers that a very simple and convenient instrument for its measurement was described before the Physical Society of London some time ago by Mr. A. P. Chattock. The instrument consists of a long solenoid of many turns wound on an elastic core so as to be flexible. One end of the helix is kept fixed while the other is moved quickly between the two places whose difference of magnetic potential is required. The ends of the coil are connected with a ballistic galvanometer and the impulse imparted to the needle is a measure of the potential difference required. This instrument might be useful in measuring the quantities referred to by Mr. Swinburne, and it seems clear that some such instrument would be of use in dynamo tests and in dynamo design.

The twenty or thirty persons who composed Mr. Heaviside's audience at the Society of Arts on Tuesday afternoon were evidently too deeply concerned with the [illegible] of cheap postage rates to pay much heed to his theories concerning telegraph cable rates, or to criticise too nicely the manner of his advocacy. People however who can be got to a five o'clock meeting of that kind are mostly enthusiasts and may perhaps be excused for patiently, though sadly, listening to Mr. Heaviside's indignant insinuations against unnamed opponents. The Chairman was apparently the only person to realise the compromising position in which the readers of the Paper was placing the Society. Addressing the meeting at the conclusion of the discussion, Sir Lyon Playfair remarked that it was not to be expected that all would agree with views put forward on that platform, but so long as they were expressed with moderation and fairness, the Society was always ready to give them a hearing.

We cannot help thinking from this and other indications that the Chairman's ideas of moderation and fairness [illegible] somewhat shocked by various passages in Mr. Heaviside's [illegible] and we shall be much disappointed if some of [illegible] mentioned before the Paper gets published in the [illegible]. The Society must guard against its [illegible] being [illegible] and intemperate [illegible].

3444

At Bath the "solid" system is being used for high-tension alternating-current and arc-lighting wires.

Besides the systems already described, the Callender Company, as is well known, also make conduits on the Callender-Webber system. This is a drawing-in-and-out system, with a separate hole for each cable. Messrs. Callender state that their experience of cables drawn into pipes several together is that, although it may be possible to add single cables when required, yet that the cables will overlay each other and get interlaced

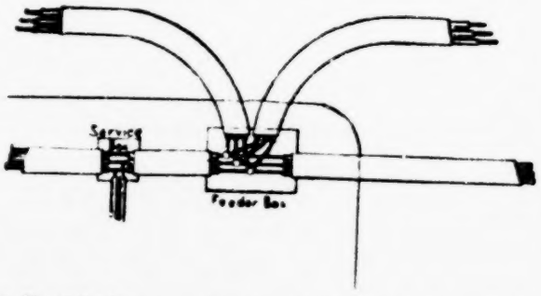

Fig. 20.—Callender Company's system. General method of running the mains and feeders (plan).

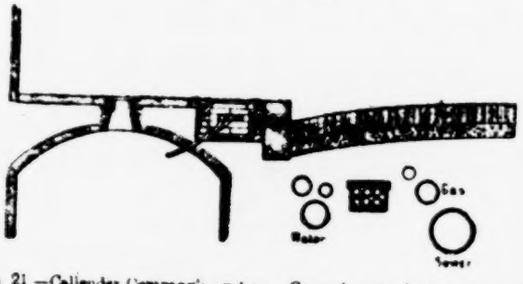

Fig. 21.—Callender Company's system. General method of running the mains and feeders (section).

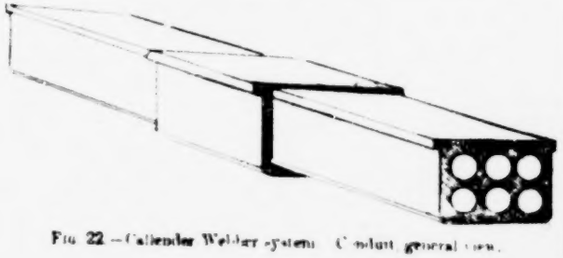

Fig. 22.—Callender Webber system. Conduit general view.

Fig. 23. Callender Webber system. Method of covering joints.

in such a way that it is very difficult to withdraw any one of them afterwards should it need repair. Figs. 20 and 21 show in plan and section the general method of running the feeders and mains. The feeders are usually carried under the road way and the service mains under the footpaths.

There are various ways in which the conduits are formed, according to the purpose for which they are to be used and the size of the cables they will have to carry. In the form which the Chelsea Electric Light Company are using the cases are laid plain, without further protection, but in the work which has been put down for Messrs. A. and S. Gatti in the Strand, the bitumen conduit is enclosed in a three-sided iron trough, which is used upside down; that is, there is iron above but none below where the conduit rests on the ground. Figs. 22 and 23 show the general form of the conduits, the method of packing them, and of covering the joints. These bitumen conduits with the holes through them are made to project a couple of inches at each end beyond their iron case. To join them together, two are brought end to end, and the mandrils of the proper size pushed through the holes into the next block so that they pass through the joints. The bitumen is then poured over the joint and the conduits pressed against its neighbour. A short piece of iron troughing of the same shape as the longer pieces containing the conduit is then made hot and slipped over the joint, melting the bitumen to some extent and making everything perfectly solid and water-tight. After the joint has had time to cool sufficiently, the mandrils are withdrawn, and the laying of the next section proceeded with. The Callender Company state that they are able to draw long lengths of cable into these conduits and to withdraw them if necessary.

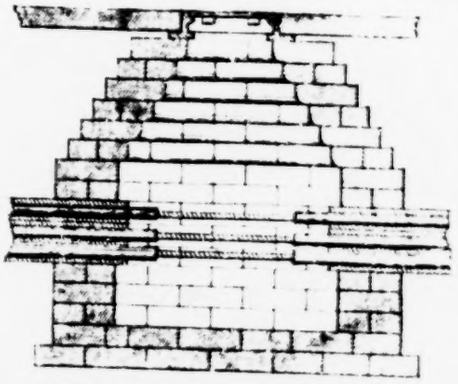

Fig. 24.—Callender-Webber system. Manhole.

Junction boxes and manholes are used with this system as per sketch (Fig. 24), being arranged to suit the requirements of each special case.

It will be noticed that in joining together the sections in the Callender-Webber system the blocks are simply made continuous, nothing being used at the joints. This is a somewhat important point, as the paper tubes used to keep the holes free at the joints, in work somewhat on the same lines in America, have proved a considerable source of subsequent trouble. It has often been objected to this class of conduit that it may crack, but in practice it is not found to do so; the bituminous being of a slightly viscous nature, has always a certain amount of give in it.

Conclusion.

The description of the leading systems of laying underground mains at present in use is now concluded, and a tabulated list is appended giving the methods and systems employed in some of the best known installations, which in this form it is hoped may prove useful, and to which the editor will be glad to receive any additions.

PROBLEMS IN THE PHYSICS OF AN ELECTRIC LAMP.*

BY PROF. J. A. FLEMING, M.A., D.SC., M.R.I.

More than eighty years ago Sir Humphrey Davy provided the terminal wires of his great battery of 2,000 pairs of plates with rods of carbon, and, bringing their extremities in contact, obtained for the first time a brilliant display of the electric arc.† The years that have fled away since that time have seen all the marvellous developments of electro magnetic engineering, have placed in our possession the electric glow lamp, and brought the art of electrical illumination to a condition in which it progresses each year with giant strides. In addition to the importance attaching to their ever increasing industrial use, there are many questions of purely scientific interest which present themselves to our minds when we proceed to examine the actions that take place when a carbon conductor is rendered incandescent in a high vacuum, or when an electric arc is formed between two carbon poles. It is to a very few of these physical problems that I desire to direct your attention to-night, but more especially to one which is particularly interesting from the bearing which it has on the general nature of electric discharge.

We know as a very familiar fact that if we attempt to raise the temperature of a carbon conductor enclosed in a vacuum beyond a certain limit, not far removed from the melting point of platinum, the carbon begins to volatilise with great rapidity. If an electric glow lamp has passed through its carbon more than a certain strength of current, the glass bulb speedily becomes darkened by a deposit of this volatilised carbon condensed upon it; and experience shows us that we cannot raise the temperature of that carbon beyond a definite point without causing this waste of the conductor to become very rapid. In the highly rarefied atmosphere within the bulb of a glow lamp, the carbon, when at its normal incandescence, must be considered to be projecting off molecules of carbon in all directions, partly in virtue of purely thermal actions, but probably also in consequence of certain electrical effects to be presently discussed. This scattering of the material of the carbon conductor takes place with disadvantageous rapidity from an industrial point of view at and beyond a certain temperature,* but it exists as well at much lower temperatures than that which is found to determine the practical limit of durability. A curious appearance is found in many incandescent lamps which have been "over run," which shows us that this projection of carbon molecules from the hot conductor is not, perhaps, best described by calling it a vaporisation of its substance, but that the surface molecules are shot off in straight lines, and that they reach the glass envelope without being hindered to any great extent by the molecules of the residual air.

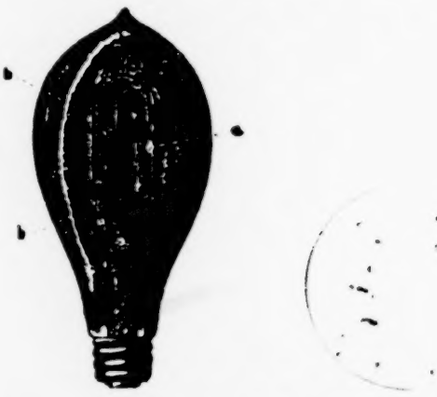

Fig. 1.—Glow lamp having the glass bulb blackened by deposit of carbon. Molecular scattering having taken place at a, and shadow of loop of deposit produced at b.

If an electric current is passed through an otherwise uniform carbon conductor, which possesses at any one place a specific resistance higher than that of the remaining portion, the current, in accordance with a well known law, there develops a higher temperature, and the molecular scattering at that spot may in consequence be greatly exaggerated. It may be that the deterioration of the conductor at that locality will be so great as to cut it through after a very short time. When the carbon has the form of a simple horseshoe loop, and when this molecular scattering takes place from some point in the middle of one branch, the molecular projection makes itself evident by producing a "molecular shadow" of the other leg upon the interior of the glass. I will project upon the screen an image of the carbon horseshoe loop taken from an old glow lamp, and you will be able to see that the filament has been cut through at one place. At that position some minute congenital defect caused the carbon to have a higher resistance, the temperature at that point when it was in use became excessive, and an intensified molecular scattering took place from that locality. On examining the glass bulb from which it was taken, we find that the glass has been everywhere darkened by a deposit of the scattered carbon except along one narrow line, (see Fig. 1), and that line is in the plane of the carbon loop and on the side opposite to the point of rupture of the filament.

* A discourse delivered at the Royal Institution on Friday evening, February 14, 1890.

† Sir Humphrey Davy had a request before the managers of the Royal Institution on July 11, 1808, that they would set on foot a subscription for the purchase of a large galvanic battery. The result of the suggestion was that a galvanic battery of 2,000 pairs of copper and zinc plates were set up in the Royal Institution, and one of the earliest experiments performed with it was the production of the electric arc between carbon poles on a large scale. It is probable, however, that Davy had produced the light on a small scale some six years before, and according to Quetelet, observed the arc between carbon points in 1802. See De Parr "Life of Sir H. Davy."

* When the rate of expenditure of energy in the carbon conductor is raised until it reaches a value of about 500 watts or 360 foot pounds per second per square inch of heated surface, a limit of useful temperature has been reached for practical working, under the usual present conditions of construction of glow lamps and in electric glow lamps.

3116

I might illustrate to you by a very simple experiment the way in which that "shadow" has been formed. Here is a ⋂-shaped rod: this shall represent the carbon conductor in the lamp; this sheet of cardboard placed behind it, the side of the glass receiver. I have affixed a little spray-producer to one side of the loop, and from that point blow out a spray of inky water. Consider the ink spray to represent the carbon atoms shot off from the overheated spot. We see that the cardboard is bespattered on all points except along one line where it is sheltered by the opposite side of the loop. We have thus produced a "spray shadow" on the board (Fig. 2). The existence of these molecular shadows in incandescent lamps leads us therefore to recognise that the carbon atoms must be shot off in straight lines, or else obviously no such sharp shadow could thus be formed. This phenomenon confirms in a very beautiful manner the deductions of the Kinetic theory of gases. I may remind you that at the ordinary temperature and pressure the mean free path of a molecule of air is deduced to be about four one-millionths of an inch. This is the average distance which such a gaseous molecule moves over before meeting with a collision against a neighbour which changes the direction of its path. Let the air be rarefied, as in these bulbs, to something like a millionth of the ordinary atmospheric pressure, and the mean free path is increased to several inches. The space within the bulb—though from one point of view densely populated with molecules of residual air—is yet, as a fact, in such a condition of rarefaction that a carbon molecule projected from the conductor can move over a distance of three or four inches on an average without meeting with interference by collision with another molecule, and the facts revealed to us by these shadows show that this must be the case. I have also at hand some Edison lamps in which these "molecular shadows" are finely shown, but in these cases the deposit on the interior of the bulb is not carbon but copper, because the molecular scattering has here taken place by excessive temperature developed at the copper clamps by which the carbon filament is attached to the platinum wires.

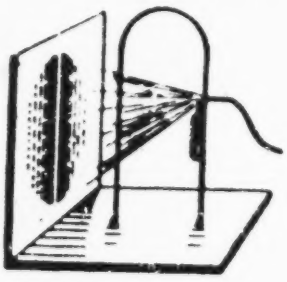

FIG. 2.—"Spray shadow" of a rod thrown on blotting paper screen to illustrate formation of molecular shadow in glow lamps.

The theory, however, is the same. The deposit of copper shows a fine green colour by transmitted light in the thinner portions. One curious lamp also before me had by an accident an aluminium plate volatilised within the bulb. The glass receiver has in consequence been covered with a mirror-like deposit of aluminium, which on the thinner portions shows a fine blue colour by transmitted light, and a silvery lustre by reflected light. This lamp also shows a fine "molecular shadow."

These facts prepare us to accept the view that when a glow-lamp is in operation the highly rarefied residual air in the interior of the bulb is being traversed in all directions by multitudinous carbon atoms projected off from the incandescent carbon conductor. I now wish to pass in review before you some facts which indicate that these carbon atoms *carry* with them electric charges, and that they are charged, if at all, with *negative electricity*. I may preface all by saying that much of what I have to show you will be seen to be closely related to the phenomena studied by Mr. Crookes in his splendid and classical researches on radiant matter. Our starting point for this purpose is a discovery made by Mr. Edison in 1884, and which received careful examination at the hands of Mr. Preece in the following year,* and by myself more recently. Here is the initial experiment. A glow-lamp having the usual horseshoe-shaped carbon (see Fig. 3) has a metal plate held on a platinum wire sealed through the glass bulb. This plate is so fixed that it stands up between the two sides of the carbon arch without touching either of them. We shall illuminate the lamp by a continuous current of electricity, and for brevity's sake speak of

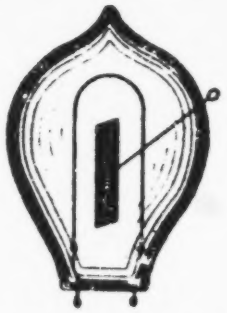

FIG. 3.—Glow lamp having insulated metal. Middle plate M sealed into bulb to exhibit "Edison effect."

that half of the loop of carbon on the side by which the current enters it as the negative leg, and the other half of the loop as the positive leg. The diagram in Fig. 4. shows the posi-

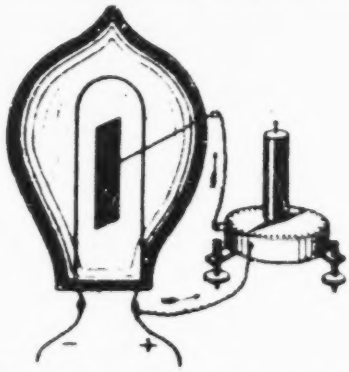

FIG. 4.—Sensitive galvanometer connected between the middle plate and positive electrode of a glow lamp, showing current flowing through it when the lamp is in action ("Edison effect").

tion of the plate with respect to the carbon loop. There is a distance of half an inch, or in some cases many inches, between either leg of the carbon and this middle plate. Setting the

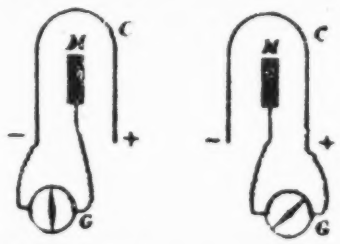

FIG. 5.—Mode of connection of galvanometer G to middle plate M and carbon-horse shoe shaped conductor C in the experiment of the "Edison effect."

lamp in action, I connect a sensitive galvanometer between the middle plate and the *negative terminal* of the lamp, and you see that there is no current passing through the instrument. If, however, I connect the terminals of my galvanometer to the middle plate and to the *positive electrode* of the lamp, we find a current of some milliamperes in passing through it. The diagrams in Fig. 5 show the mode of connection

* W. Preece's interesting Paper on this subject is published in the *Proceedings of the Royal Society* for 1885, p. 219. See also *The Electrician*, April 4, 1885, p. 436.

3012

of the galvanometer in the two cases. This effect, which is often spoken of as the "Edison effect," clearly indicates that an insulated plate so placed in the vacuum of a lamp in action is brought down to the same potential or electrical state as the negative electrode of the carbon loop. On examining the direction of the current through the galvanometer we find that it is equivalent to a flow of negative electricity taking place through it *from* the middle plate *to* the positive electrode of the lamp. A consideration of this fact shows us that there must be some way by which negative electricity gets across the vacuous space from the negative leg of the carbon to the metal plate, whilst at the same time a negative charge cannot pass from the metal plate across to the positive leg. Before I pass away from this initial experiment, I should like to call your

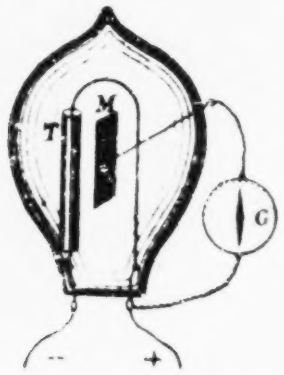

FIG. 6.—Glow lamp, having negative leg of carbon enclosed in glass tube. The "Edison effect" thereby being annulled or greatly lessened.

attention to a curious effect at the moment when the lamp is extinguished. Connecting the galvanometer as at first, between the middle plate and the negative electrode of the lamp, we notice that though made highly sensitive the galvanometer indicates no current flowing through it whilst the lamp is in action. Switching off the current from the lamp-producer, as you see, a violent kick or deflection of the galvanometer, indicating a sudden rush of current through it

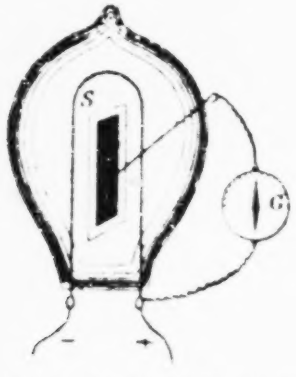

FIG. 7.—Glow lamp having one leg of carbon enclosed in glass tube, S, interposed between middle plate M and the negative leg of carbon thereby lessening the Edison effect.

In endeavouring to ascertain further facts about this effect one of the experiments which early suggested itself was one directed to determine the relative effects of different portions of the carbon conductor. Here is a lamp (see Fig. 6) in which one leg of the carbon loop has been enclosed in a glass tube of the size of a quill which shuts in one half of the carbon. The bulb contains, as before, an insulated middle plate. If we pass the actuating current through this lamp in such a direction that the covered or shielded leg is the *positive* leg, we find the effect existing as before. A galvanometer connected between the plate and positive terminal of the lamp yields a strong current, say of deflection 60 between the negative terminal and the middle plate there is no current at all. Let us, however, reverse the current through the lamp so that the shielded or enclosed leg is now the negative one, and the galvanometer is able to detect no current, whether connected in one way or in the other. We establish, therefore, the conclusion that it is the negative leg of the carbon loop which is the active agent in the production of this "Edison effect," and that if it is enclosed in a tube of either glass or metal, no current is found flowing in a galvanometer connected between the positive terminal of the lamp and this middle collecting plate.

Another experiment which confirms this view is as follows:—This lamp (see Fig. 7) has a middle plate, which is provided with a little mica flap or shutter on one side of it. When the lamp is held upright the mica shield falls over and covers one side of the plate, but when it is held in a horizontal position the mica shield falls away from the front of the plate and exposes it. Using this lamp as before we find that when the positive leg of the carbon loop is opposite to the shielded face of the plate, we get the "Edison effect" as before in any position of the lamp. Reversing the lamp current and making that same leg the *negative* one, we find that when the lamp is so held the metal plate is shielded by the interposition of the mica, and the galvanometer current is very much less than when the shield is shaken on one side and the plate exposed fully to the negative leg.

(To be continued.)

Problems in the Physics of an Electric Lamp[1]

By Prof. J. A. Fleming, M.A., D.SC., M.R.I.

(Concluded from page 395.)

At this stage it will perhaps be most convenient to outline briefly the beginnings of a theory proposed to reconcile these facts, and leave you to judge how far the subsequent experiments confirm this hypothesis. The theory very briefly is as follows: From all parts of the incandescent carbon loop, but chiefly from the negative leg, carbon molecules are being projected which carry with them, or are charged with, negative electricity. I will in a few moments make a suggestion to you which may point to a possible hypothesis on the manner in which the molecules acquire this negative charge. Supposing this, however, to be the case, and that the bulb is filled with these negatively charged molecules, what would be the result of introducing into their midst a conductor such as this middle metal plate which is charged positively? Obviously, they would all be attracted to it and discharge against it. Suppose the positive charge of this conductor to be continually renewed, and the negatively-charged molecules continually supplied, which conditions can be obtained by connecting the middle plate to the positive electrode of the lamp, the obvious result will be to produce a current of electricity flowing through the wire or galvanometer, by means of which this middle plate is connected to the positive electrode of the lamp. If, however,

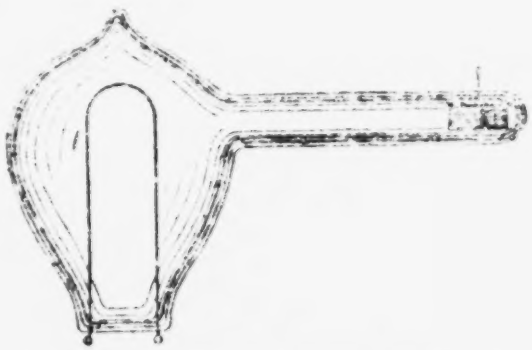

FIG 5. Collecting plate placed at end of tube in line of length, opening out of bulb

[1] A discourse delivered at the Royal Institution on Friday evening, February 14, 1890.

the middle plate is connected to the negative electrode of the lamp, the negatively-charged molecules can give up no charge to it, and produce no current in the interpolated galvanometer. We see that on this assumption the effect must necessarily be diminished by any arrangement which prevents these negatively-charged molecules from *de*ing shot off the negative leg or from striking against the middle plate. Another obvious corollary from this theory is that the "Edison effect" should be annihilated if the metal collecting plate is placed at a distance from the negative leg much greater than the mean free path of the molecules.

Here are some experiments which confirm this deduction. In this bulb (Fig. 8) the metal collecting plate, which is to be connected through the galvanometer with the positive [fol. 3017] terminal of the lamp, is placed at the end of a long tube opening out of and forming part of the bulb. We find the "Edison effect" is entirely absent, and that the galvanometer current is zero. We have, as it were, placed our target at such a distance that the longest range molecular bullets cannot hit it, or, at least, but very few of them do so. Here again is a lamp in which the plate is placed at the extremity of a tube opening out of the bulb, but bent at right angles (Fig. 9). We find in this case, as first discovered by Mr. Preece, that there is no "Edison effect." Our molecular marksman cannot shoot round a corner. None of the negatively charged molecules can reach the plate, although that plate is placed at a distance not greater than would suffice to produce the effect if the bend were straightened out. Following out our hypothesis into its consequences would lead us to conclude that the material of which the plate is made is without influence on the result, and this is found to be the case. Many of the foregoing facts were established by Mr. Preece as far back as 1885, and I have myself abundantly confirmed his results.

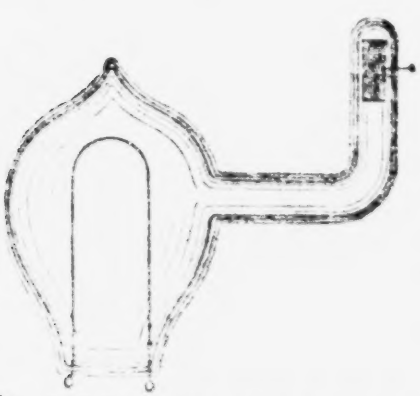

Fig. 9. Collecting plate placed at end of a bent tube opening out of bulb.

We should expect also to find that the larger we make our plate, and the nearer we bring it to the negative leg of the carbon, the

greater will be the current produced in a circuit connecting this plate to the positive terminal of the lamp. I have before me a lamp with a large plate placed very near the negative leg of the carbon of a lamp, and we find that we can collect enough current from these molecular charges to work a telegraph relay and ring an electric bell. The current which is now working this relay is made up of the charges collected by the plate from the negatively-charged carbon molecules which are projected against it from the negative leg, across the highly perfect vacuum. I have tried experiments with lamps in which the collecting plate is placed in all kinds of positions, and has various forms, some of which are here, and are represented in the diagrams before you; but the result may all be summed up by saying that the greatest effects are produced when the collecting plate is as near as possible to the base of the negative end of the loops, and, as far as possible, encloses, without touching, the carbon conductor. Time will not permit me to make more than a passing reference to the fact that the magnitude of the current flowing through the galvanometer when connected between the middle plate and the positive terminal of the lamp often "jumps" from a low to a high value, or *vice versâ*, in a remarkable manner, and that this sudden change in the current can be produced by bringing strong magnets near the outside of the bulb.

Let us now follow out into some other consequences this hypothesis that the interior of the bulb of a glow lamp when in action is populated by flying crowds of carbon atoms all carrying a negative charge of electricity. Suppose we con- [fol. 3018] nect our middle collecting plate with some external reservoir of electric energy, such as a Leyden jar, or with a condenser equivalent in capacity to many hundreds of Leyden jars, and let the side of the condenser which is charged positively be first placed in connection through a galvanometer with the middle plate (see Fig. 10), whilst the negative side is placed in connection with the earth. Here is a condenser of two microfarads capacity so charged and connected. Note what happens when I complete the circuit and illuminate the lamp by passing the current through its filament. The condenser is at once discharged. If, however, we repeat the same experiment with the sole difference that the negatively charged side of the condenser is in connection with the middle plate then there is no discharge. The experimental results may be regarded

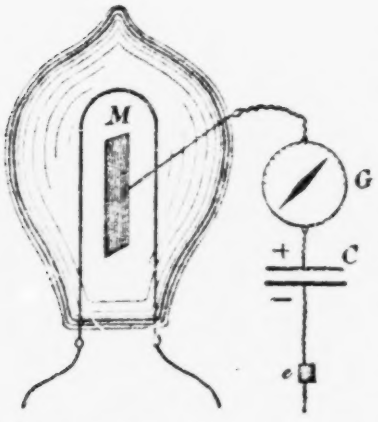

FIG. 10.—Charged condenser C discharges by middle plate M, when the positively charged side of condenser is in connection with the plate and other side to earth e.

from another point of view. In order that the condenser may be discharged as in the first case it is essential that the negatively charged side of the condenser shall be in connection with some part of the circuit of the incandescent carbon loop. This experiment with the condenser discharged by the lamp may be then looked upon as an arrangement in which the plates of a charged condenser are connected respectively to an incandescent carbon loop and to a cool metal plate, both being enclosed in a highly vacuous space, and it appears that when the incandescent conductor is the negative electrode of this arrangement the discharge takes place, but not when the cooler metal plate is the negative electrode of the charged condenser. The negative charge of the condenser can be carried across the vacuous space from the hot carbon to the colder metal plate, but not in the reverse direction.

This experimental result led me to examine the condition of the vacuous space between the middle metal plate and the negative leg of the carbon loop in the case of the lamp employed in our first experiment. Let us return for a moment to that lamp. I join the galvanometer between the middle plate and the negative terminal of the lamp, and find, as before, no indication of a current. The metal plate and the negative terminal of the lamp are at the same electrical potential. In the circuit of the galvanometer we will insert a single galvanic cell having an electromotive force of rather over one volt. In the first place let that cell be so inserted that its negative pole is in connection with the middle plate, and its positive pole in connection through the galvanometer with the negative terminal of the lamp (see Fig. 11). Regarding the circuit of that cell alone, we find that it consists of the cell itself, the galvanometer wire, and that half inch of highly vacuous space between the hot carbon conductor and the middle plate. In that circuit the [fol. 3019] cell cannot send any sensible current at all, as

it is at the present moment connected up. But if we reverse the direction of the cell so that its positive pole is in connection with the middle plate, the galvanometer at once gives indications of a very sensible current. This highly vacuous space, lying between the middle metal plate on the one hand and the incandescent carbon on the other, possesses a kind of unilateral conductivity, in that it will allow the current from a single galvanic cell to pass one way but not the other. It is a very old and familiar fact, that in order to send a current from a battery through a highly rarefied gas by means of metal electrodes, the electromotive force of the battery must exceed a certain value. Here, however, we have indication that if the negative electrode by which that current seeks to enter the vacuous space is made incandescent the current will pass at a very much lower electromotive force than if the electrode is not so heated.

A little consideration of the foregoing experiments led to the conclusion that in the original experiment, as devised by Mr. Edison, if we could by any means render the middle plate very hot, we should get a current flowing through a galvanometer when it is connected between the middle plate and the negative electrode of the carbon. This experiment can be tried in the manner now to be shown. Here is a bulb (Fig. 12) having in it two carbon loops; one of these is of ordinary size and will be rendered incandescent by the current from the mains. The other loop is very small, and will be heated by a well insulated, secondary battery. This smaller incandescent loop shall be employed just as if it were a middle metal plate. It is in fact, simply an incandescent middle conductor. On repeating the typical experiment with this arrangement we find that the galvanometer indicates a current when connected between the middle loop and either the positive or the negative terminal of the main carbon. I have little doubt but that if we could render the platinum plate in our first-used lamp incandescent by con-

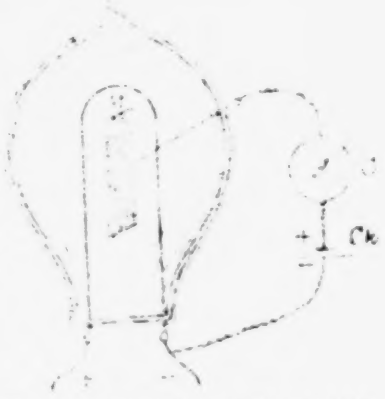

Fig. 12.—Current from Clark cell (Ck) through vacuous space between carbon loop (–) and middle plate M. Positive pole of cell in connection with plate M through galvanometer G.

centrating on it from outside a powerful beam of radiant heat we should get the same result.

A similar set of results can be arrived at by experiments with a *a* bulb constructed like an ordinary vacuum tube, and having small carbon loops at each end instead of the usual platinum or aluminum wires. Such a tube is now before you (see Fig. 13), and will not allow the current from a few cells of a secondary battery to pass through it when the carbon loops are cold. If, however, by means of well insulated secondary batteries we render both of the carbon loop electrodes highly incandescent, a single cell of a battery is sufficient to pass a very considerable current across that vacuous [fol. 3020] space provided the resistance of the rest of the circuit is not large. We may embrace the foregoing facts by saying that if the electrodes, but especially the negative electrode, which form the means of ingress and egress of a current into a vacuous space are capable of being rendered highly incandescent, and if at that high temperature they are made to differ in electrical potential by the application of a very small electromotive force, we may get under these circumstances a very sensible current through the rarefied gas. If the electrodes are cold a very much higher electromotive force will be necessary to begin the discharge or current through the space.* These facts have been made the subject of elaborate investigation by Hittorf and Goldstein, and more recently by Elster and Geitel. It is to Hittorf that I believe we are indebted for the discovery of the fact that by heating the negative electrode we greatly reduce the apparent resistance of a vacuum.

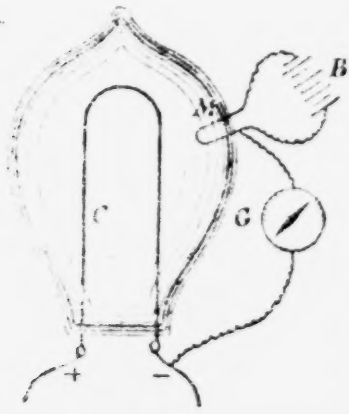

FIG. 13.—Experiment showing that when the "middle plate" is a carbon loop rendered incandescent by an insulated battery *B*, a current of negative electricity flows from *M* to the positive leg of main carbon *C* across the vacuum.

Permit me now to pave the way by some other experiments for a little more detailed outline of the manner in which I shall venture to suggest these negative molecu-ar charges are bestowed. This is really the important matter to examine. In seeking for some probable explanation of the manner in which these wandering molecules of carbon in the glow-lamp bulb obtain their negative charges, I fall

back for assistance upon some facts discovered by the late Prof. Guthrie. He showed some years ago new experiments

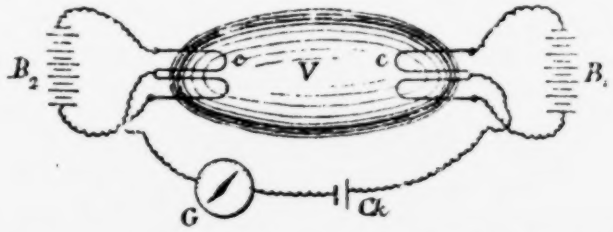

FIG. 13.—Vacuum tube having carbon loop electrodes, cc, at each end rendered incandescent by insulated batteries, B_1 B_2, showing current from Clark cell, CA, passing through the high vacuum when the electrodes are incandescent.

on the relative powers of incandescent bodies for retaining positive and negative charges. One of the facts he brought forward [2] was that a bright red-hot iron ball, well insulated, could be charged negatively, but could not retain for an instant a positive charge. He showed this fact in a way which it is very easy to repeat as a lecture experiment. Here is a gold-leaf electroscope, to which we will impart a positive charge of electricity, and project the image of its divergent leaves on the screen. A poker the tip of which had been made [fol. 3021] brightly red hot is placed so that its incandescent end is about an inch from the knob of the electroscope. No discharge takes place. Discharging the electroscope with my finger, I give it a small charge of negative electricity, and replace the poker in the same position. The gold leaves instantly collapse. Bear in mind that the extremity of the poker when brought in contiguity to the knob of the charged electroscope becomes charged by induction with a charge of the opposite sign to that of the charge of the electroscope, and you will at once see that this experiment confirms P of. Guthrie's statement, for the negatively-charged electroscope induces a positive charge on the incandescent iron, and this charge cannot be retained. If the induced charge on the poker is a negative charge it is retained, and hence the positively-charged electroscope is not discharged, but the negatively-charged electroscope at once loses its charge. Pass in imagination from iron balls to carbon molecules. We may ask whether it is a legitimate assumption to suppose the same fact to hold good for them, and that a hot

[2] "On a New Relation between Electricity and Heat," *Phil., Mag.*, Vol. XLV, p. 308. 1873.

carbon molecule or small carbon mass just detached from an incandescent surface behaves in the same way and has a greater grip for negative than for positive charge? If this can possibly be assumed, we can complete our hypothesis as follows: Consider a carbon molecule or small congerie of molecules just set free by the high temperature from the negative leg of the incandescent carbon horseshoe. This small carbon mass finds itself in the electrostatic field between the branches of the incandescent carbon conductor (*see* Fig. 14). It is acted upon inductively, and if it behaves like the hot iron ball in Prof. Guthrie's experiment it loses its positive charge. The molecule then being charged negatively is repelled along the lines of electric force against the positive leg. The forces moving it are electric forces, and the repetition of this action would cause a torrent of negatively charged molecules to pour across from the negative to the positive side of the carbon horseshoe. If we place a metal plate in their path, which is in conducting connection with the positive electrode of the lamp carbon, the negatively-charged molecules will discharge themselves against it. A plate so placed may catch more or less of this stream of charged molecules which pour across between the heels of the carbon loop. There are many extraordinary facts, which as yet I have been able only imperfectly to explore, which relate to the sudden changes in the direction of the principal stream of these charged molecules, and to their guidance under the influence of magnetic forces. The above rough sketch of a theory must be taken for no more than it is worth, viz., as a working hypothesis to suggest further experiments.

FIG. 14.—Rough diagram illustrating a theory of the manner in which projected carbon molecules may acquire a negative charge.

These experiments with incandescent lamps have prepared the way for me to exhibit to you some curious facts with respect to the electric arc, and which are analogous to those which we have passed in review. If a good electric [fol. 3622] arc is formed in the usual way, and if a third insulated carbon held at right angles to the other two is placed so that its tip just dips into the arc (*see* Fig. 15), we can show a similar series of experiments. It is rather more under control if we cause the arc to be projected against

the third carbon by means of a magnet. I have now formed on the screen an image of the carbon poles and the arc between them in the usual way. Placing a magnet at the back of the arc, I cause the flame of the arc to be deflected laterally and to blow against a third insulated carbon held in it. There are three insulated wires attached respectively to the positive and to the negative carbons of the arc, and to the third or insulated carbon, the end of which dips into the flame of the arc projected by the magnet. On starting the arc this third carbon is instantly brought down to the same electrical potential as the negative carbon of the arc, and if I connect this galvanometer in between the negative carbon and the third or insulated carbon I get, as you see, no indication of a current. Let me, however, change the connections and insert the circuit of my galvanometer in between the positive carbon of the arc and the middle carbon, and we find evidence, by the violent impulse given to the galvanometer that, there is a strong current flowing through it. The direction of this current is equivalent to a flow of negative electricity from the middle carbon through the galvanometer to the positive carbon of the arc. We have here then the "Edison effect" repeated with the electric arc. So strong is the current flowing in a circuit connecting the middle carbon with the positive carbon that I can, as you see, ring an electric bell and light a small incandescent lamp when these electric-current detectors are placed in connection with the positive and middle carbons.

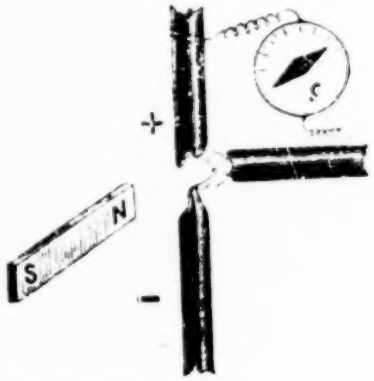

FIG. 15.—Electric arc projected by magnet against a third carbon, and showing strong electric current flowing through a galvanometer, G, connected between the positive and third carbon.

We also find that the flame-like projection of the arc between the negative carbon possesses a unilateral conductivity. I join this small secondary battery of fifteen cells in series with the galvanometer, and connect the two between the middle carbon and the negative carbon of the arc. Just as in the analogous experiment with the incandescent lamp, we find we can send negative electricity along the flame of

the arc one way but not the other. The secondary battery causes the galvanometer to indicate a current flowing through it when its negative pole is in connection with the negative carbon of the arc (*see* Fig. 16), but not when its positive pole is in connection with the negative carbon. On examining the third or middle carbon after it has been employed in this way for some time we find that its extremity is cratered out and converted into graphite, just as if it had been employed as the positive carbon in forming an electric [fol. 3023] arc. Time forbids me to indulge in any but the briefest remarks on these experiments; but one suggestion may be made, and that is that they seem to indicate that the chief movement of carbon molecules in the electric arc is *from* the negative *to* the positive carbon. The idea suggests itself that, after all, the cratering out of the positive carbon of the arc may be due to a sand-blast action of this torrent of negatively-charged molecules, which are projected from the negative carbon. If we employ a soft iron rod as our lateral pole, we find that, after enduring for some time the projection of the arc against it, it is converted at the extremity into *steel*.

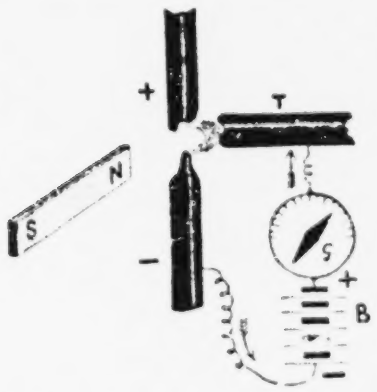

Fig. 16. Galvanometer *G* and battery *B* inserted in series between negative carbon of electric arc and a third carbon to show unilateral conductivity of the arc between the negative and third carbons.

Into the fuller discussion as to the molecular actions going on in the arc, the source and nature of that which has been called the counter-electromotive force of the arc, and the causes contributing to produce unsteadiness and hissing in the arc, I fear that I shall not be able to enter, but will content myself with the exhibition of one last experiment, which will show you that a high vacuum or, indeed, any vacuum, is not necessary for the production of the "Edison effect." Here is a carbon-horseshoe-shaped conductor, not enclosed in any receiver (see Fig. 17). Close to the negative leg or branch, yet not touching it, we have adjusted a little metal plate. The sensitive galvanometer is connected between this metal plate and the

base of the other or positive leg of this carbon arch. On sending a current through the carbon sufficient to bring it to bright incandescence, the galvanometer gives indications of a current flowing through it, and as long as the carbon endures, which is not, however, for many seconds, there is a current of electricity through it equivalent to a flow of negativ electricity from the plate through the galvanometer to the positive electrode of the carbon. The interposition of a thin sheet of mica between the metal plate and the negative leg of the carbon loop entirely destroys the galvanometer current.[3]

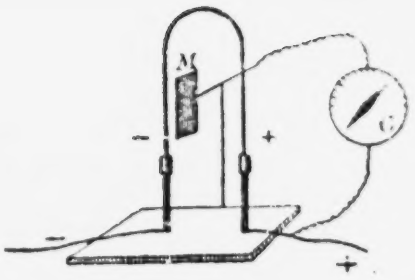

FIG. 17.—"Edison effect" Experiment shown with carbon in open air.

These experiments and brief expositions cover a very small portion of the ground which is properly included within the limits of my subject. Such fragments of it as we have been able to explore to-night will have made it clear [fol. 3024] that it is a region abounding in interesting facts and problems in molecular physics. The glow lamp and the electric arc have revolutionised our methods of artificial lighting, but they present themselves also as subjects of scientific study, by no means yet exhausted of all that they have to teach.

[fol. 3025-3026] DEFENDANT'S EXHIBIT M-1

Transactions of American Institute of Electrical Engineers, 1897

The second part of this paper, which relates to the conductivity of the vacuous space surrounding incandescent filaments, may be considered as a discussion of the paper upon the "Edison Effect" in incandescent lamps, which was read before the INSTITUTE by Professor Houston, in October, 1884, and which was the first paper read before this society.

[3] This last experiment is due to my assistant, Mr. A. H. Bate.

"Edison Effect" is the name given to the effect produced by those currents, first observed by Mr. Edison, which pass from one leg of an incandescent filament across the vacuous space to the other leg, and which can be observed by connecting a galvanometer between the positive lamp terminal and a wire sealed into the bulb and projecting into the vacuous space.

FIG. 4

Figure 4, which is taken from Professor Houston's paper, serves to illustrate Mr. Edison's original experiment. The galvanometer indicates a current flowing from the positive lamp terminal through the galvanometer and third lamp wire, and through the vacuous space to the negative leg of the incandescent filament. If the external connection of the galvanometer be changed from the positive terminal to the negative terminal, no current will flow through the galvanometer. This effect can be observed in the most highly exhausted lamps. A lamp so highly exhausted that it shows no glow when tested with an induction coil, giving a spark $\frac{3}{4}$" long, will allow a current sufficiently large to show plainly on a not very sensitive galvanometer, to pass through its vacuous space. This current increases as the temperature of the filament is increased, but in a well exhausted lamp is never greater than a very few milliamperes, when the lamp is burned at about $2\frac{1}{2}$ watts per candle.

In 1884 Mr. Preece secured from Mr. Edison some lamps having wires sealed into the bulbs, and read a paper before the Royal Society describing some experiments made upon them, illustrating the "Edison Effect."

Professor Fleming read a most elaborate paper before the Physical Society of London, in March, 1896, upon this same subject. Professor Fleming's experiments proved that in well exhausted lamps the vacuum is not a conductor in the ordinary sense of the word, and that the current which passes through it is carried by negatively charged [fol. 2027] molecules, which pass constantly from the negative leg of the incandescent filament to the positive leg and to any inserted wire, thus bringing the inserted wire to the same potential as the negative leg. Professor Fleming also proved that these molecules pass in straight lines, and that their passage is completely or almost completely stopped by a glass or mica screen placed between the negative leg and

the inserted wire. The following experiments serve to illustrate these effects:

Figure 5 shows a lamp having a glass tube surrounding one leg of the filament, and a wire sealed in the side of the bulb, which projects into the centre of the vacuous space. When the leg of the filament which is in the glass tube is made positive, and the filament heated to about a $2\frac{1}{2}$ watts-per-candle temperature, the galvanometer, which is connected between the wire and the positive lamp terminal, shows a strong deflection, but when the leg in the tube is

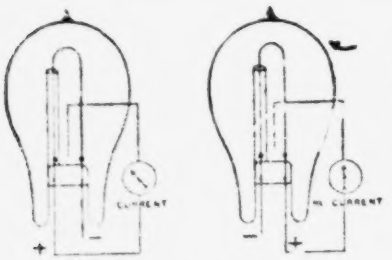

Fig. 5.

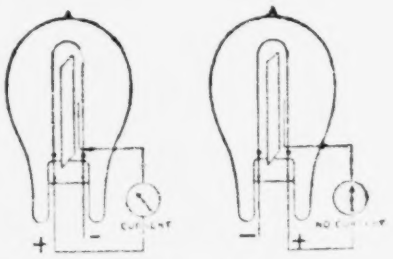

Fig. 6.

made negative, the galvanometer, being as before connected between the wire and the positive lamp terminal, shows no deflection.

Figure 6 shows a lamp having a platinum plate $2\frac{1}{4}$" long and $\frac{3}{4}$" wide between the legs of the filaments, and a wire inserted in the vacuous space. I also used lamps having a similar plate made of glass, similarly placed. In both of these lamps, when the vacuum was high, no current was produced between the wire and the positive terminal when the wire was shielded from the negative leg; but shielding the wire from the positive leg made no hindrance to the passage of the current. The facts that no current flows when the galvanometer is connected between the negative terminal of the lamp and the inserted wire, and that a shield between the positive leg and the inserted wire has no effect upon the current, show that positively charged molecules are not emitted by the positive leg; while the screen effects just described show that the negatively charged molecules pass in straight lines.

The facts, then are these: The galvanometer indicates a current flowing, as we designate the direction of currents, from the wire to the negative leg; while experiments prove that the charged molecules which carry the current actually pass from the negative leg to the wire. These facts

are entirely in accord with the results obtained by Crookes and others in their investigations of currents in high vacua. [fol. 3028] If an alternating current is used to render the filament incandescent, the galvanometer will indicate a current with the connection made to either lamp terminal, because both are equally positive. The current thus produced is a uni-directional one in the galvanometer, and illustrates very well the uni-lateral conductivity between the incandescent filament and the wire.

Mr. Preece states in his paper that lamps which show a blue glow in the vacuous space give stronger "Edison Effects" than those which do not show it. Professor Fleming also observes that poorly exhausted lamps give slightly greater effects, but neither of them paid much attention to these lamps.

The blue glow in lamps has long been associated in my mind with a condition of the vacuum which makes it a conductor. Lamps in the process of exhaustion, just before the vacuum is perfected, show this blue very plainly, if a little more than normal current is sent through the filament. The blue increases as the current is increased and becomes very dense at very high temperatures. This blue indicates a current passing from one leg of the filament across the vacuous space to the other leg.

I observed several years ago, that at a high temperature .04 or .05 of an ampere more current flowed through a lamp showing a good blue than through the same lamp, at the same voltage, when the blue had disappeared. I concluded that this extra current flowed through the vacuous space between the legs of the filament.

If a direct current about 20 or 30 per cent. greater than the normal current be passed through a lamp filament when the vacuous space shows a blue glow, the positive joint between the filament and the platinum wire gets red hot, while the negative joint remains cool.

I have always considered this as proof that the resistance to the passage of a current through a vacuous space was chiefly at the surface of the positive electrode, as the energy was chiefly developed there. If an alternating current is used, both joints get equally hot.

If a lamp be burned at normal incandescence with a direct current, when the vacuous space shows a good deal of this blue, the negative leg of the filament becomes coated with a carbon soot. This effect can be obtained in a few minutes

if the blue is dense and the filament is run above a normal incandescence. This I have considered to be due to an electrolysis of a hydrocarbon gas in the lamp.

The lamps which show only a slight amount of this blue glow, if burned at normal incandescence, will not show this carbon soot perceptibly, and the blue will entirely disappear if the lamp is burned for a few hours. This blue is caused more by the character of the residual gas than by the degree of exhaustion. Lamps having a residual of bromine vapor do not show it at all, neither do they show any "Edison Effect." I have seen ordinary lamps ready to be sealed off the pumps which showed blue and then no blue, and blue again, at regular intervals of a few seconds. Such lamps show corresponding changes in the "Edison Effect."

[fol. 3029] If the current be gradually increased in a lamp which shows good blue, the positive joint will get hotter and hotter and finally its platinum wire will fuse. At this stage the resistance to the flow of current across the vacuous space is not great, and if the conditions are such that at this time all the resistance in circuit with the lamp has been cut out, so that the current flowing will be practically determined by the resistance of the lamp and the leads, enough current will flow through the vacuous space to

* * * * * * *

showing about as strong effects as 140-volt lamps. The energy they exhibit in one direction seems to be very much

Fig. 7

greater than we would expect from molecules actuated by a potential difference of only 40 or 50 volts. The action of these molecules in carrying electricity in one direction only, may be an indication of the nature of the action between

molecules in solid conductors carrying currents, rather than an illustration of the action of statically charged molecules.

Discussion

Mr. John W. Howell: After I had written this paper, I broke the lamp having the graphite filament and took the filament out—a part of it—and measured its specific resistance. Its specific resistance (the resistance of a piece 1 inch long and 1 circular mil area) was 450 ohms. The lowest specific resistance I have ever measured of amorphous carbon is about 2200 ohms. The treatment obtained by hydrocarbon deposit is about 350 ohms, which is about six or seven times as low; and this graphite lamp was 450 ohms, which was very nearly the figure of the carbon obtained by treatment, and I think if it had been a more solid graphite it would have been lower. I can also say that the specific gravity of graphite is practically the same as the specific gravity of the carbon obtained by hydrocarbon deposit.

The President: How was that filament made?

Mr. Howell: It was simply made by making a die, filling it with graphite and solidifying it under great pressure—so great pressure that it made a solid graphite filament of it. [fol. 3030] Dr. A. E. Kennelly: I believe that I voice the general sentiment in saying that this is a very interesting paper, both by reason of what it contains of investigation and by reason of what it suggests for further inquiry.

I remember having taken part in the measurements of resistance in the lamp filament referred to. I believe that the theory given in this paper was suggested at that time for the apparently abnormal behavior of its resistances, but the additional evidence was not then forthcoming which enables Mr. Howell to make so strong a case for that theory in this paper.

It is perhaps no more surprising that graphite should differ markedly from ordinary carbon in its temperature coefficient of resistivity, than that diamond should differ markedly from ordinary carbon in its hardness.

Incidentally it is curious to observe from the curves in the paper that approximately five per cent. of the voltage needed to produce an inefficiency of three watts per candle, raised the temperature of the filaments experimented on to 500° F., or 260° C.

It has long been known that the passage of a continuous current through a Geissler tube set up a series of pulsatory currents or discharges, which are capable of producing alternating currents in a separate circuit, through the intermediary of an alternating current transformer. So far as I know, however, it has been pointed out for the first time in this paper, that an alternating current passed through an incandescent lamp giving the "Edison Effect" is capable of producing in a branch circuit through a third wire in a lamp, continuous or at least undirectional currents. Consequently it is interesting to observe that a vacuum tube, in the broadest sense of the term, is capable of supplying not only alternating currents from continuous currents, but also continuous currents from alternating currents.

As regards the results obtained in the interesting manner described, it would appear that some of these observations differ from those quoted as obtained by Dr. Fleming. It would seem that Dr. Fleming took the position that the blue discharge can only travel in straight lines, whereas in some of the experiments here referred to, as, for example, those in connection with Figs. 11 and 12, the blue discharge and the "Edison Effect" did apparently go around a corner, and a sharp corner too.

I am unable to follow the conclusion mentioned by Mr. Howell, that the change in the development of heat from the positive joint to the middle wire, when the connections are changed, indicates that no bombardment can take place. It seems to me possible that bombardment might still take place under a directive influence determined by the point of connection. No doubt Mr. Howell can make this matter clear.

Mr. E. A. Colby: I am deeply interested in Mr. Howell's paper, especially the latter part of it, referring to the so called "Edison Effect." While I am not prepared to-night [fols. 3031-3032] to present any theory as to the phenomena observed, I can say that the characteristics which Mr. Howell has mentioned are well known to me. I would like to ask if he has substituted for the galvanometer which he used in measuring the currents, the still more sensitive instrument, the telephone, and whether he has attempted with its aid to explore the vacuous space by the insertion of platinum

wires at different points in the glass bulb. Some years ago I tried an experiment of this character which was described in a discussion before the Institute. I sealed into a lamp bulb in the plane of the filament a number of platinum wires about one inch apart. Connecting the terminals of the telephone with the positive leg of the lamp, and with one of these wires I observed a note in the telephone which varied in pitch according to the position of the wire sealed into the bulb. When the telephone was connected to the positive leg on one side, and to the platinum terminal which was nearly at the middle of the filament, or more correctly on the diagonal to positive terminal of the area enclosed by the legs of the filament, I obtained the maximum note, and as I carried this terminal of the telephone near to the negative leg of the filament I got practically no sound whatever. I also inserted in a similar

Proceedings of Physical Society of London, March 27, 1896

XVII. A Further Examination of the Edison Effect in Glow Lamps. By J. A. Fleming, M.A., D.Sc. F.R.S., Professor of Electrical Engineering in University College, London [1]

1. The experiments described in this paper had for their object the further examination of an effect which can be produced in certain forms of electric incandescence lamps and to which attention was first drawn by Mr. Edison in 1884. This effect may be generally described as follows: A carbon filament incandescence lamp having the ordinary horse-shoe loop carbon has a metallic plate placed in the exhausted bulb, the plate being carried on a platinum wire sealed through the globe, and fixed so as to stand up between the legs of the horse-shoe (see fig. 1). If the lamp is set in action at the usual incandescence by a continuous current of the proper strength, and a suitable sensitive galva-

[1] Read March 27, 1896

nometer is connected between the insulated metal plate and the *positive* terminal of the lamp, it will in general be found to indicate a current of some milliamperes flowing through it. The direction of this current is *from* the positive electrode of the lamp through the galvanometer *to* the insulated metal plate, or wire. When the same galvanometer is connected between the *negative* pole of the lamp and the middle plate, unless it is very sensitive, it indicates no current. This effect was very carefully examined by Mr. W. H. Preece in 1885, and he subjected it to a systematic examination by the aid of a number of lamps having such metal plates [fol. 3034] placed in various positions.[2] By this observer a number of very interesting facts were collected, the result of which was to point out the general nature of the phenomenon. A sufficient number of new questions were, however, suggested by the information so acquired to invite further inquiry. Whilst confirming and re-examining the experimental results obtained by Mr. Preece, some facts that

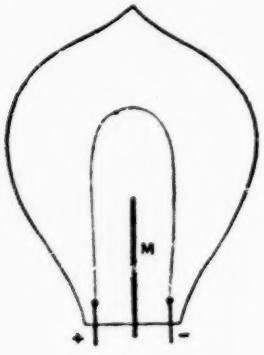

FIG. 1.

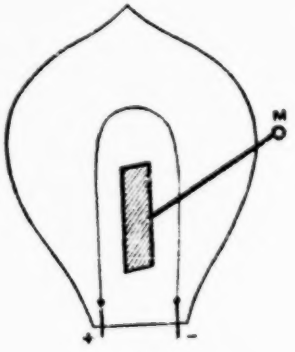

FIG 2.

had previously escaped notice presented themselves, which it is the object of this paper to describe.

§ 2. The first experiments were made with a lamp of the form shown in fig. 2, similar to some used by Mr. Preece in his experiments. A metal plate, generally of aluminum, is

[2] "On a Peculiar Behaviour of Glow-Lamps when raised to High Incandescence," by W. H. Preece, F.R.S. Proceedings of the Royal Society, 1885, p. 219.

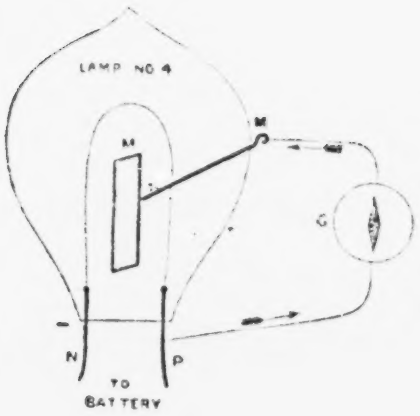

FIG. 3

supported on a platinum wire sealed through the bulb or glass receiver, the plate being so fixed that its plane is at right angles to the plane of the loop of the carbon, and as nearly as possible midway between the legs. The plate therefore projects between the legs of the horse-shoe carbon, and the carbon conductor arches over it without touching it. The plate is entirely insulated from the carbon.

The preliminary experiments with this normal type of middle-plate lamp consisted in determining the effective potential difference between the third terminal and one or other of the two electrodes of the carbon filament when the lamp was subjected to varying steady electromotive forces sufficient to raise the temperature of the carbon from dull red to vivid incandescence, and in determining the magnitude of the current flowing in a circuit connecting the middle plate with one or other of the electrodes of the lamp.

3. *Experiment 1.*—An ordinary carbon filament electric lamp, having the horse-shoe shaped conductor, had a plati- [fol. 3035] num plate (see fig. 3) about 2.5 centimetres long by 1.5 centimetres wide welded to a platinum wire, sealed through the side of the bulb. The plate was so placed as to project between the legs of the carbon conductor, having its plane at right angles to the plane of the horse-shoe, and initially fixed about halfway between the two legs. This lamp will be described in the subsequent paragraphs as Lamp No. 4. Under a steady electromotive force of 40 volts, this lamp took .3 amperes when working at the normal temperature corresponding to about 3.5 watts per candle-power. When a milliamperemeter having a resistance of 6872 ohms was joined between the base P of the *positive* leg of the carbon (see fig. 4) and the middle plate M, a current was found passing through the galvanometer from the terminal P to the plate M. This current had a magnitude of

about 3 milliamperes when the carbon was in the normal state of incandescence.

If the milamperemeter was connected between the negative electrode of the lamp and the middle plate, no current perceptible by this galvanometer was found. On replacing the milamperemeter by a more sensitive Elliott mirror galvanometer (resistance 7142 ohms) it was found that a small

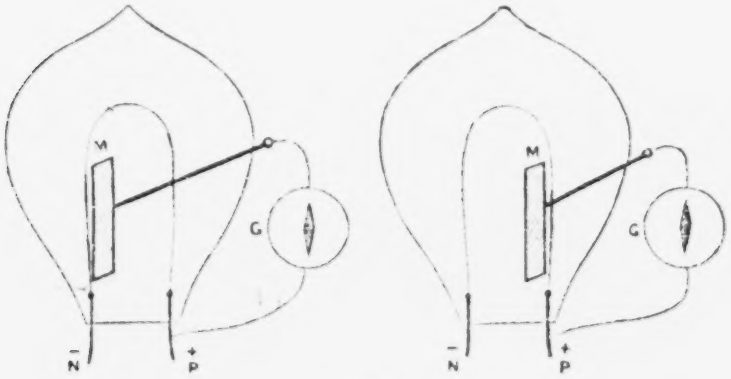

Fig. 4.

current passed through it, when joined in between the negative electrode of the lamp and the middle plate, but that this current had a magnitude hardly exceeding .0001 of a milliampere when the lamp was at its normal incandescence.

In order to avoid repetition, it may be here said that, unless otherwise stated, the terminal of the lamp in connexion with the positive pole of the working battery will be spoken of as the positive electrode of the lamp; that in connexion with the negative pole of the battery as the negative electrode. For brevity's sake, the half of the carbon filament between the centre of the filament and the positive electrode will be called the *positive leg*, and the other half the *negative leg*.

4. A preliminary series of experiments was made with lamp No. 4 by placing the lamp in a photometer and deter- [fol. 3536] mining the watts per candle-power and the current taken by the lamp corresponding to various working electromotive forces, taken over the whole range of electromotive force from that necessary just to render the filament incandescent to the highest the lamp could with safety endure. In any subsequent experiments, the simple measurement of the potential-difference between the electrodes of

the lamp enabled the rate of dissipation of energy in the filament and the watts per candle power to be deduced. It may here be remarked that in the preliminary experiments some difficulties arose from the occlusion of residual gas by the middle metal plate, but finally this was overcome, and the vacuum in these experimental bulbs made and preserved as perfect as in good ordinary commercial lamps. The following results were then obtained with this lamp No. 4. The lamp was raised to various degrees of incandescence by varying the working volts by the aid of a rheostat in series with the lamp.

The milliamperemeter was employed to measure the effective potential-difference between the positive electrode of the lamp and the middle plate and then, tabulating against the working volts of the lamp the current in milliamperes flowing through the galvanometer, the potential-difference between the middle plate and the positive electrode of the lamp was calculated from these figures. The results are given in the table below (Table No. 1).

TABLE No. 1. *Lamp No. 4, milliamperemeter*

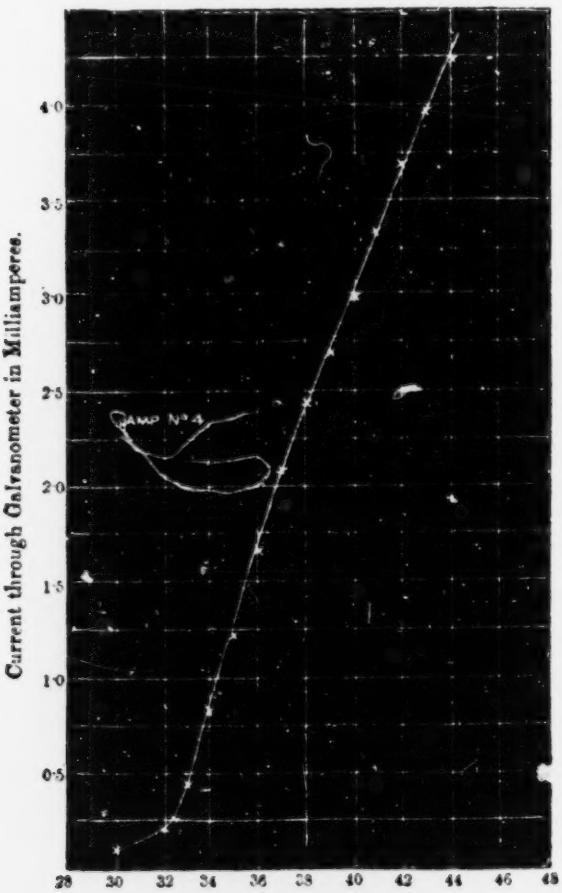
Table showing the volts between the middle plate and the positive electrode, and the current flowing through a galvanometer of 6372 ohms resistance connecting them, taken for various working voltages of the lamp.

Working volts of lamp	Volts between plate and positive lamp electrode	Current in milliamperes through galvanometer	Working volts of lamp	Volts between plate and positive lamp electrode	Current in milliamperes through galvanometer
30	54	085	36	10 7	1 69
32	1 2	190	37	12 7	2 01
32 5	1 6	25	38	14 9	2 36
33	2 8	44	39	17 1	2 71
33 5	4 7	74	40	18 9	2 99
34	5 3	84	41	21 4	3 37
34 5	7 1	1 12	42	23 4	3 71
35	7 8	1 23	43	25 2	3 99
			44	26 8	4 25

The results given in table No. 1 are plotted in curve No. 1, in which horizontal abscissae represent to scale the working volts of the lamp and vertical ordinates the milliampere currents through the galvanometer. It will be seen that the curve representing the current from lamp electrode to plate takes a rather sharp turn upwards at a point corresponding to 35 working volts, and this occurs when the

lamp is working at about 7.8 watts per candle-power. Beyond this point the curve is very approximately a straight line. Accordingly, at and beyond the volts at which the carbon filament becomes fairly well incandescent, [fol. 3037] the effective potential-difference between the

TABLE No. 1.—*Curve No. 1*



middle plate and the positive lamp electrode is very nearly a linear function of the lamp voltage; and at the normal working volts, viz. 40 volts, this potential-difference between the middle plate and the positive electrode so determined is apparently about half that between the lamp terminals, the plate being nearly midway between the carbon legs. The results given in Table 1 are the mean of several observations, but it was noticed that when the lamp was main-

tained at a steady voltage, the potential-difference between the middle plate and the positive electrode would often *jump suddenly* from one value to another. This effect renders it difficult to obtain the stable values of the plate and positive electrode potential-difference. Corresponding to any definite steady voltage on this lamp, the current may have one or other of two values, but not always permanently preserving either; a galvanometer deflection indicating say [fol. 3038] 10 volts between the plate and positive electrode of the lamp will often slowly increase until after a few minutes it is 12 or 14 volts, yet all the time the working volts on the lamp are remaining perfectly constant. It will then often suddenly jump perhaps to 22 volts, and then slowly decrease to 19 volts, or so. This tendency of the potential-difference between the middle plate and positive lamp electrode to jump from a low to a high value, or *vice versâ*, is most marked in lamps in which the plate is about half-way, and symmetrically placed, between the legs of the carbon. We shall speak of these two values as the high and low value of the current through the galvanometer, and defer until later a discussion of some other causes tending to make the current pass from a high to a low value or the reverse, as well as its possible explanation. In Table No. 2 are tabulated a set of observations on the same lamp No. 4, showing these double values which the potential-difference and current may have, and it may be here noted that in the previous Table No. 1, the higher values have been taken in those cases in which double values exist.

TABLE No. 2.—*Lamp No. 4, milampèremeter.*

Table showing the multiple values of the potential-difference between the middle plate and positive electrode of the lamp corresponding to various given working voltages.

Working volts of the lamp	Volts between the middle plate and positive electrode of the lamp	Current through the graded galvanometer in milli-amperes	Working volts of the lamp	Volts between the middle plate and positive electrode of the lamp	Current through the graded galvanometer in milli-amperes

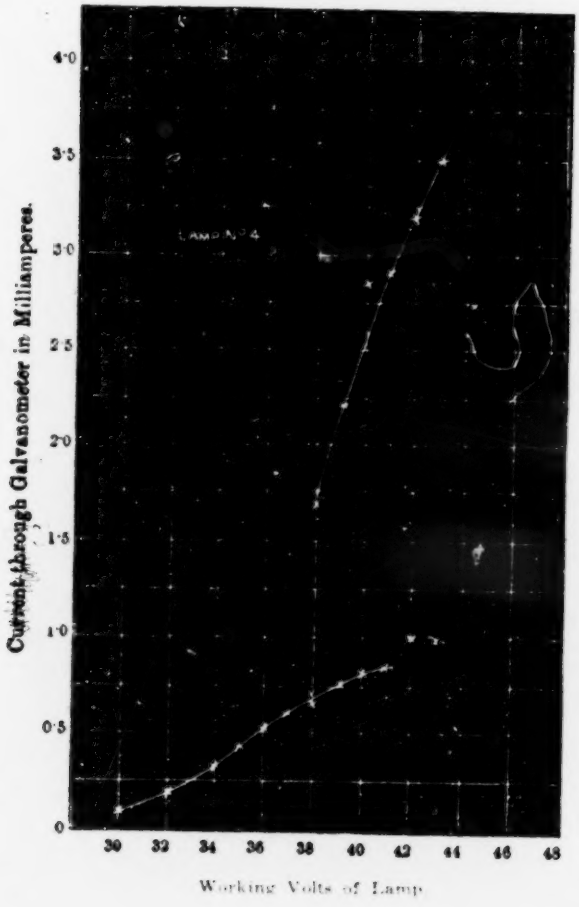
			"	22 0	3 49

These observations are plotted in Curve No. 2, in which the abscissæ represent the working volts of the lamp and the ordinates the current in milliamperes flowing through the galvanometer connecting the positive electrode and the middle plate. It is seen that corresponding to any working pressure above 38 volts for this lamp, which is equivalent

TABLE No. 2.—*Curve No. 2*



to 4.2 watts per candle-power, there are two possible values of the effective potential-difference between the middle plate and the positive electrode. As the working voltage of the lamp is gradually raised, the reading of the galvanometer inserted between the middle plate and positive electrode is also increased, but there is a great tendency to jump from a certain low value to a higher one, and this occurs

when the working pressure of the lamp is preserved steady. There is also an effect produced by the presence of a magnet near the lamp bulb. When the current is at the low value corresponding to any working voltage, the galvanometer reading does not seem to be perceptibly altered by bringing [fol. 3039] a magnet near the lamp, but when it is at its high value, the reading is sometimes increased for a little, showing a steady deflexion, and then immediately falls to its low value.

5. *Experiment 2.*—The difference of potential between the middle plate and the positive electrode of the lamp depends to a considerable extent upon the position of the middle plate. Supposing the plate to be placed with its plane perpendicular to the plane of the carbon horse-shoe and then moved to various positions between the two legs of the carbon, it is found that the difference of potential between the plate and the positive electrode will have different values according to the position of the plate. This fact was elucidated by means of the same lamp No. 4 as used above. By carefully tapping the lamp, the supporting platinum wire carrying the platinum middle plate could be bent so as to displace the plate from its symmetrical position as regards the two carbon legs, and bring it nearer to one or other of the legs. In several different positions the current flowing through the milamperemeter, when connected between the middle plate and positive electrode, was [fol. 3040] measured, the lamp being kept meanwhile at the same working electromotive force.

Estimating as nearly as possible the fractional distances, the plate was placed at distances from the negative leg equal to $^1/_{10}$, $^1/_4$, $^1/_2$, $^3/_4$, and $^9/_{10}$ of the whole distance between the positive and negative legs, and the lamp being taken through a definite cycle of volts, the potential-difference between the middle plate and the positive electrode was measured with the milamperemeter. The results are collected in the following tables. The diagrams in fig. 6 represent the horse-shoe carbon loop and the middle plate M in various positions, the galvanometer G being inserted between the plate M and the positive electrode P. By the phrase "whole distance" in the following tables is meant the whole distance or width of the space between the positive and negative carbon leg.

TABLE No. 3.—*Lamp No. 4, milliampere meter*

Table showing the potential-difference between the middle plate and positive electrode of the lamp at various positions of the plate and at various working voltages.

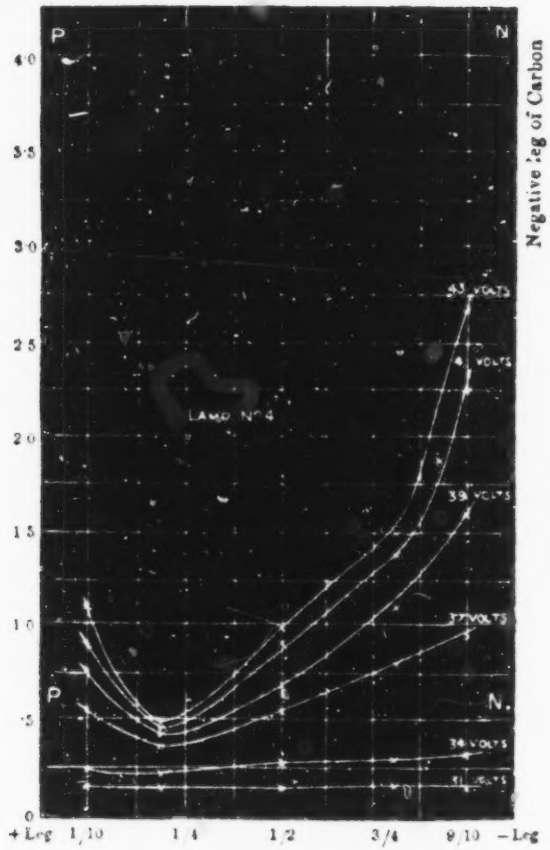
[fol. 3041] The results of this Table No. 3 are plotted in the curves No. 3. These curves are to be interpreted as follows:—The two vertical lines P and N represent the two legs of the carbon horse-shoe. At various distances on the way from P to N the milliampere current through a galvanometer connected between the middle plate, placed at that point, and the positive electrode of the lamp is represented by the magnitude of the vertical ordinate of each curve. For every one of the different voltages at which the lamp is worked, there is therefore a curve representing by its ordinates this current strength through a galvanometer inserted between the middle plate, placed at these positions, and the positive electrode of the lamp, and it is seen that there is a *minimum value* for this current at a position

TABLE No. 3.—*Curve No. 3*

The middle plate was moved along into different positions between the two carbon legs indicated by the horizontal distances, and at each position the current between the middle plate and positive electrode of the lamp is represented by the vertical ordinate of a curve. The several curves correspond to different working volts on the lamp.



Position of Plate between legs

equal to $\frac{2}{3}$ of the whole distance between the legs reckoned from the negative leg.

[fol. 3042] Imagine the middle plate therefore connected through a galvanometer with the positive electrode of the lamps, and let the middle plate be first placed close to the positive leg and then moved continuously nearer towards the negative leg. The current through the galvanometer would first fall off as the plate receded from the positive leg, and after reaching a minimum at a point about $\frac{1}{4}$ of the whole distance between the legs reckoned from the positive leg, would rise up to a maximum when the middle plate was as nearly in contact with the negative leg as possible without actually touching it.

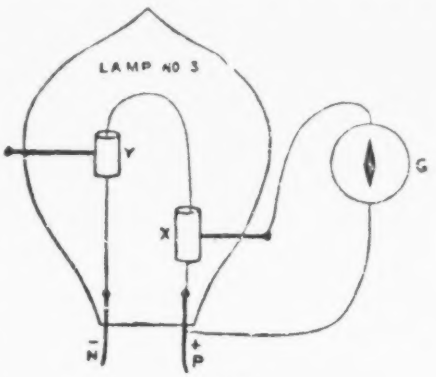


Fig. 5.

6. *Experiment 3.* In order to explore more thoroughly the action of the different portions of the incandescence carbon conductor in producing this effect, a lamp was taken having a horse-shoe shaped carbon, and a pair of small platinum cylinders, held on platinum wires sealed through the glass, so placed as to embrace without touching the carbon conductor. One of these cylinders, X, was placed so as to embrace the carbon near the bottom of the leg, and the other, Y, near the spring of the arch (see fig. 5). These small cylinders had a length of about 12 millims. and a diameter of about 8 millims. so that the distance from the

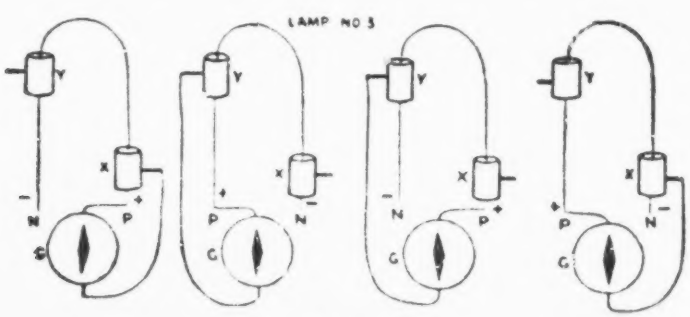

Fig. 6.

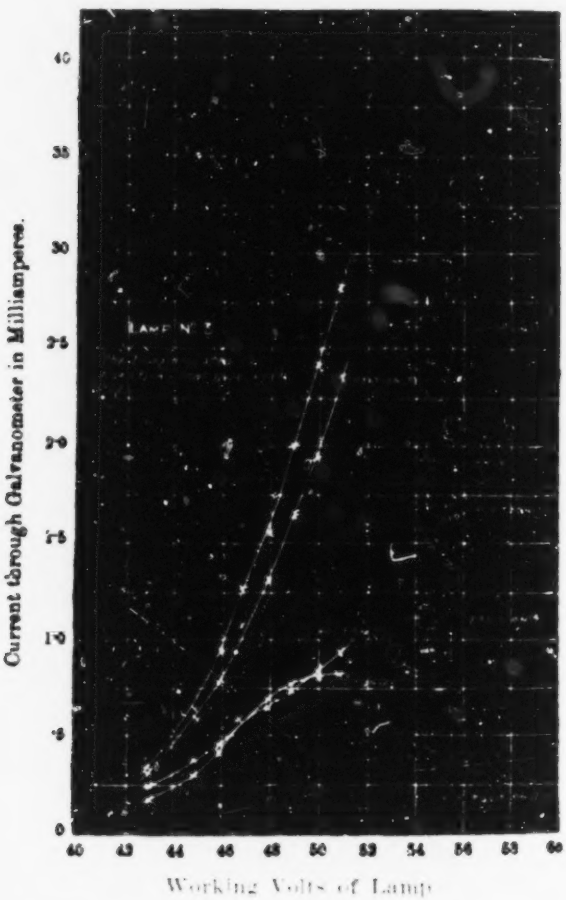
Position (1) Position (2) Position (3) Position (4)

carbon filament to the inner surface of the cylinder was about 3 or 4 millims. The lamp had a rather thick carbon, and at an electromotive force of 48 volts took a current of 1.32 amperes to raise it to its normal incandescence of 18.8 candles, corresponding to 3.3 watts per candle-power. This lamp will be alluded to as Lamp No. 3.

TABLE No. 4.—*Curve No. 4*



It is obvious that there are four possible arrangements in which a current can be obtained between an embracing [fol. 3043] cylinder and a positive electrode of the lamp. These are illustrated in fig. 6, in which the horse-shoe shaped line stands for the carbon filament, X and Y are the platinum cylinders, P and N are the positive and negative electrodes of the lamp, and G is the galvanometer.

We will call these arrangements (1), (2), (3), (4), as

figured. It will be seen that if we imagine the carbon filament straightened out, these four arrangements are equivalent to being able to slide a cylinder along the filament into four positions, and in each position measuring the potential-difference between the cylinder and the positive end of the carbon. We are thus able to place an embracing collecting-plate at four different places along the carbon conductor, and determine the potential difference between this embracing cylinder and the positive electrode of the lamp. A series of experiments was made with lamp No. 3, in which the working volts of the lamp were raised to various values, and in each case the potential-difference between one of the cylinders X or Y and the positive electrode of the lamp was observed as before by means of the milamperemeter. The results are given in Table 4.

TABLE No. 4.—*Lamp No. 3, milamperemeter*

Table showing the potential-difference between a platinum cylinder embracing the carbon and the positive electrode of the lamp, and the current flowing through the galvanometer in milliamperes; for the four positions shown in fig. 6.

Working volts of the lamp	Volts between cylinder and positive electrode	Current in milliamperes through the galvanometer	Working volts of the lamp	Volts between cylinder and positive electrode	Current in milliamperes through the galvanometer

50	12·3	1·95	50	15·1	2·38
51	14·9	2·36	51	18·0	2·85

These observations are plotted in Curve No. 4

[fol. 3044] This table of observations shows us that taking the lamp at any definite voltage, the potential-difference be-

tween the positive electrode and a cylinder embracing the carbon filaments is greatest when that cylinder is as low down near the foot of the negative leg of the carbon as possible. If the cylinder is placed near the top of the negative leg that potential-difference becomes less. If the cylinder is taken near the top of the positive leg or near the base of the positive leg it is least, and it seems to be a minimum when the cylinder surrounds the top of the positive leg, and is as far as possible away from the foot of the negative leg. We have here a confirmation of the fact observed with respect to lamp No. 4, viz.: that the potential-difference between the positive lamp electrode and the metal plate held somewhere near the incandescent carbon conductor is greatest when the plate is as near as possible to the foot of the negative leg or negative electrode.

In this lamp No. 3, in which in all positions the cylinder employed is placed very near some point on the incandescing [fol. 3045] conductor, the current through the galvanometer joining the positive electrode and the cylinder has never been observed to jump or to take double values as in the case of lamp No. 4.

If a sensitive galvanometer is connected to the two insulated cylinders X and Y, and if in addition there is a battery in series with this galvanometer, then no current can be detected in such an arrangement even when the battery has an electromotive force of 120 volts, whether the lamp carbon is incandescent or not. Just as in the case of lamp No. 4, the current obtained by connecting either cylinder with the negative electrode of the lamp is excessively small.

In order to obtain curves showing the mode of variation of the effective difference of potential between one or other of the metal cylinders X and Y and the positive electrode of the lamp, a set of observations was made on the lamp when submitted to various working voltages, and at the same time the milliamperemeter was connected first between the positive electrode and cylinder X and then between the positive electrode and cylinder Y, with the following tabulated results (p. 204).

These results, when plotted out in curves in which horizontal ordinates represent the working volts of the lamp and the vertical ones the milliampere currents going through the galvanometer, in both cases have the same general form as curve No. 1 plotted for the case of lamp No. 4.

7. *Experiment 4.*—The magnitude of the current found on connecting any galvanometer between one of the cylinders and the positive electrode of the lamp was found to be [fol. 3046] dependent to some degree on the perfection of the vacuum. Lamp No. 3 when first made had not a very perfect vacuum. A series of measurements was, however, made with it, and the same repeated after re-exhaustion. The results are tabulated together below.

TABLE No. 6. *Lamp No. 3, Elliott galvanometer*

Table showing the relative values of the potential-difference between cylinder Y and the positive electrode for good and imperfect vacua in the case of lamp No. 3.

Working volts of the lamp	Very high vacuum in the lamp		Imperfect vacuum in the lamp	
	Watts per candle-power taken up in carbon	Volts between cylinder Y and positive electrode	Watts per candle-power taken up in carbon	Volts between cylinder Y and positive electrode
40	6 75	2 02	9 1	4 17
41	5 75	2 89	7 9	7 25
42	5 30	3 62	6 5	8 39
43	4 90	4 54	5 9	9 80
44	4 50	6 08	4 3	11 96
45	4 15	7 50	4 0	13 76
46	3 84	9 25	3 7	15 08
47	3 55	10 33	3 4	16 21
48	3 30	13 2	3 2	18 28
49	3 07	16 3	3 0	22 05
50	2 90	18 4	2 8	22 99
52	2 74	21 8	2 6	23 93
52	2 58	24 4	2 4	28 26

The imperfection of the vacuum is indicated by the higher watts per candle power absorbed at low voltages, and we see that at any given working pressure the potential-difference between the positive electrode and the cylinder Y embracing the top of the negative leg is *greater* when the vacuum is imperfect than when it is very good. The presence of residual air tends to bring down the potential of the embracing cylinder more nearly to that of the carbon at the point adjacent to it.

18. *Experiment 5.* A series of observations was next made in which the potential difference between the middle plate and the positive electrode was determined by the aid of a condenser. If a condenser of capacity C in microfarads is charged to a potential of V volts and discharged through a ballistic galvanometer, we can determine the ballistic constant of the galvanometer. A second observation of a like nature in which the "throw" of the same galvanometer is observed when the same condenser is charged by contact with two points concerning which we require to know the potential difference, gives us the means of calculating the electrostatic potential difference in volts. A condenser of .987 microfarad capacity carefully determined was charged to a potential of 54 volts and discharged through a certain ballistic galvanometer having a needle whose periodic time

of vibration was about three seconds. The resulting "throw" of the galvanometer was 5° 30′. Hence a discharge of $54 \times .987 = 53.3$ microcoulombs through the gal- [fol. 3047] vanometer produces a "throw" of 5° 30′. Neglecting a very small correction for the logarithmic decrement, in this case not of importance, we have for the ballistic constant R the value

$$53.3 = R \sin \tfrac{1}{2}(5° 30') = R \times .04798;$$

hence

$$R = 1110.$$

The same condenser was then connected between the middle plate and positive electrode of lamp No. 4 and then discharged through the same ballistic galvanometer. The lamp was subjected to a working pressure of 39 volts as determined by a corrected voltmeter attached to the electrodes of the lamp. The charge of the condenser was sent through the ballistic galvanometer, and a "throw" of 4° obtained. If v is the potential-difference between the middle plate and positive electrode of the lamp, we have the following equation for v in terms of the ballistic constant and angle of "throw":

$$\begin{aligned} .987\, v &= 1110 \sin 2° \\ &= 1110 \times .0349 \\ &= 111 \times 349 \end{aligned}$$

or

$$v = \frac{111 \times 349}{987} = 39 \text{ nearly.}$$

The potential-difference between the middle plate and the positive electrode as determined by this method is therefore *exactly the same* as the potential-difference between the positive and negative electrodes of the lamp. In other words, when the filament is brought to full incandescence, the middle metal plate is brought to the same potential as the negative electrode of the lamp. This observation was repeated with several other lamps having middle plates in various positions and of various forms, and always with the same result, viz., that the potential of the middle plate when insulated is brought down nearly to that of the negative electrode.

[9. *Experiment 6.*—In order to confirm the results obtained by the condenser method and to eliminate all the conditions which necessarily exist when we attempt to measure potential-difference galvanometrically, an electrostatic method of measuring the potential-difference at any instant

between the metal plate and the positive electrode of the lamp was next used. For this purpose a Kelvin multicellular electrostatic voltmeter was employed to determine the potential-difference between the positive and negative electrodes of the lamp and between the positive electrode of the lamp and the middle plate, with the following results:

A lamp (No. 4) having the plate fixed between the carbon legs was raised to various working voltages and the potential-differences above mentioned taken.

[fol. 3048]

TABLE No. 7.—*Lamp No. 4. Kelvin electrostatic voltmeter.*

Working volts of the lamp	Static potential-difference in volts between middle plate and positive electrode of the lamp
41	41
58·1	58·7
61·0	61·5

These observations confirm conclusively the previous results. The insulated metal middle plate is in this case brought to the *same potential* as the base of the negative leg of the carbon; and hence, on measuring electrostatically the potential-difference between that metal plate and the positive electrode of the lamp, we find it to be the same as the potential-difference between the two electrodes of the lamp.

10. *Experiment 7.*—In order to see if this was the case when the metal collecting plate had a very small surface placed at some distance from the negative electrode of the lamp, the lamp called No. 1 was employed. In this lamp a platinum wire [illegible] threaded through the turns of a double spiral 100 volt carbon lamp (see 11). The lamp was raised to various working voltages, and the electrostatic voltmeter employed to measure at the same time the static potential-difference between the positive electrode of the lamp and the platinum wire, with the following results:

The figures in the above Table No. 8 show that when the surface of the collecting-plate is very small and is placed some distance from the base of the negative leg of the carbon it is brought down only to the potential of some point (probably the nearest point) on the carbon conductor, and that therefore the potential-difference between the plate and positive electrode of the lamp is somewhat less than the potential-difference between the working terminals of the lamp. At the same time, however, the electrostatic voltmeter shows no measurable potential-difference between the negative terminal of the lamp and the platinum wire, and the most sensitive galvanometer between these points gives no indication of any current.

[fol. 3049] By means of the electrostatic voltmeter it was, however, ascertained that in those cases in which the metallic plate presented considerable surface (several square centimetres) and was placed so that some portion of it was not removed by more than a centimetre or two from the base of the negative leg of the carbon, it was brought down almost immediately to the potential of the negative terminal of the lamp. If the middle plate is placed at a little distance from the carbon loop then, on testing by the condenser method, it is found that the plate is not instantly brought down to the potential of the negative terminal, but that some few seconds have to elapse before this is the case.

11. A series of experiments was then undertaken in order to determine the effect of varying (1) the surface, and (2) the position of the metal plate in the bulb, and in these experiments the plate was sometimes of platinum and sometimes of aluminium. In all cases the vacuum was a very perfect one, any occluded gases in the plates being got rid of by special means.

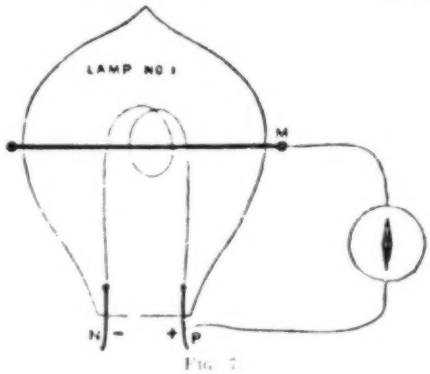

Fig. 7.

Experiment 8.—A normal 100-volt carbon-filament lamp, having a carbon filament coiled in a spiral of two turns (see fig. 7) had a short stout platinum wire (.024 inch diam.) sealed across the bulb so as to thread through, without touching, the spirals of the carbon. The lamp at 100 volts took 1.54 am-

peres and gave an illumination of 40 candles, equivalent to a power absorption of 3.9 watts per candle-power. The vacuum was very good. This lamp will hereafter be called Lamp No. 1. As before, no current could be detected by a galvanometer when joined up between the platinum wire and the negative electrode, but when the galvanometer was connected between the platinum wire and the positive electrode of the lamp a current of some milliamperes was found passing through it. As in the case of lamp No. 4, this lamp was characterized by a great tendency to change suddenly the value of the current flowing through the galvanometer when the working volts on the lamp were kept perfectly constant. In the first series of observations the milamperemeter was employed to measure the current flowing between the positive electrode of the lamp and the platinum wire when it was connected between these points, and at and beyond a working-pressure of 90 volts or so the galvanometer would often jump suddenly from one reading to another, when the lamp working volts were kept perfectly constant.

In the following table, No. 9, are collected the results when the working pressure of the lamp was gradually raised from 80 to 100 volts:

[fol. 3050] TABLE No. 9.—*Lamp No. 1, milamperometer.*

Table showing the potential difference between the positive electrode and the platinum wire, and the current flowing through the galvanometer connecting them, for various voltages of the lamp.

"	1 3	206	100	8 6	1 37
91	1 4	222	"	10 3	1 64

These figures show that at any definite working electromotive force of the lamp the current between the positive electrode and the middle plate has very variable values, and that it suddenly changes from one value to another without any apparent reason, the working volts of the lamp remaining constant all the time.

If the surface of the collecting-plate is large, say several square centimetres, the potential-difference existing between it and the positive electrode is not found to be so much reduced by attempting to measure it with a galvanometer of about 6000 ohms resistance as it is when the collecting wire presents, as in this lamp No. 1, only a small total surface of about one square centimetre.

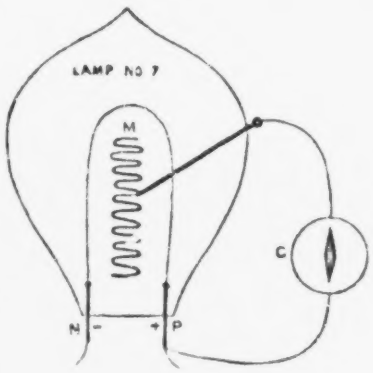

FIG. 8.

12. *Experiment 9.*—A horse-shoe carbon filament, taking 1.3 ampere of current at a working-pressure of 42.5 volts, had a middle plate made of a long piece of platinum wire bent up in a zigzag shape so as to form a rectangular-shaped grating (see fig. 8). The object of this was to ascertain whether a middle plate offering a surface pierced with many apertures was as effective in producing the current as a solid plate of about the same general outline. Practically it was found that this was the case.

The magnitude of the currents obtained at various working voltages are of the same magnitude approximately as in the case of a lamp like No. 4, that is to say some 3-4 milliamperes at full incandescence.

13. A set of experiments was then undertaken with the object of examining the special effect of varying the posi- [fol. 3051] tion of the middle plate, and a series of lamps was used in which platinum or aluminum plates held on platinum wires were placed in the lamp bulb, or in tubes opening into it, in various positions. These lamps are generally 50-volt lamps of usual type, and had single horse-shoe shaped filaments.

Experiment 10.—A lamp-bulb had a side tube blown on it (see fig. 9) and a plate about 6 centims. long and 1.5 centims. wide welded to a platinum wire was sealed into it. The platinum plate was placed vertically and edgeways in the

side tube and the side tube was in such a position that the plane of the platinum plate coincided with the plane of the horse-shoe filament. This lamp, called henceforth No. 2, when worked at 48 volts took 1.3 amperes of current and gave a light of 17.5 candles, equivalent to a power-consumption of 3.55 watts per candle-power. The vacuum was very good. In the case of this lamp the current between the positive electrode of the lamp and the platinum plate was found to be numerically very much smaller at the usual working pressure of the lamp than was found to be the case in those lamps in which the middle plate was placed between the carbon legs or in the form of a cylinder embracing the carbon.

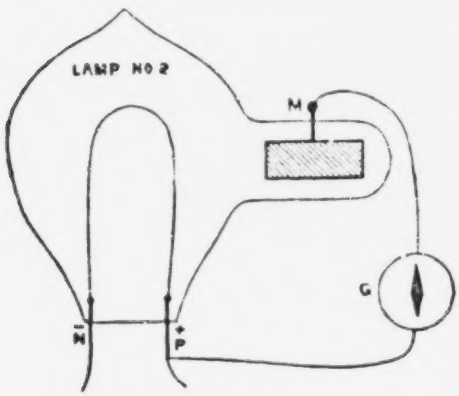

FIG. 9

The current obtained at any definite working voltage was considerably greater when the leg of the carbon nearest the plate was the *positive* leg than when it was the *negative* leg. A series of observations were taken using the lamp at different voltages and measuring with the Elliott galvanometer the potential-difference between the platinum plate and positive electrode of the lamp, and these results were as tabulated below in Table No. 10.

TABLE No. 10.—*Lamp No. 2, Elliott galvanometer*

Table showing the potential-difference between the platinum plate and the positive electrode of the lamp at various working voltages. Positive leg of carbon nearest the platinum plate.

46	4·10	156	51	2·94	352
47	3·80	172			

[Vol. 3052] If we compare together the results obtained with this lamp No. 2, in which a plate is placed edgeways on and outside the carbon loop, with the results obtained in the case of lamp No. 3, in which the plates embraced the carbon in the form of cylinders, we see the difference produced by the change of position of the plate. Both these lamps, No. 2 and No. 3, are 48-volt lamps when working at normal incandescence. Referring to Table No. 7 in § 7, we see that for lamp No. 3 at 48 volts the voltage difference of the positive electrode and the platinum cylinders was respectively 13.2 and 18.3 volts as measured with the Elliott galvanometer, and this indicated a current of about 1.3 and 1.8 milliamperes flowing through the resistances from the positive lamp electrode to the metal plate; but in the case of lamp No. 2, at 48 volts the potential-difference between the platinum plate and the positive lamp electrode was only .2 volt, and this corresponded to a current of .03 milliampere nearly. Accordingly the current is greatly diminished when the collecting-plate is placed edgeways to and someway outside the loop of the carbon. At normal incandescence the current between the positive lamp electrode and the middle plate when joined by the galvanometer is about .03 or .04 milliampere when the *positive* leg of the carbon is nearest the middle plate, but only about .02 or .03 milliampere when the negative leg is nearest the plate.

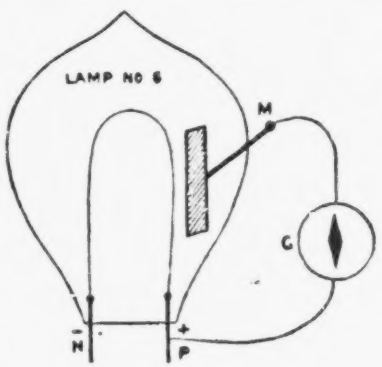

Fig. 10

14. *Experimental 1.*—In order to compare the previous results just given with those obtained when the collecting-plate was placed broadside to and yet outside the carbon loop, a lamp was made as in fig. 10 in which an aluminium plate was held on a platinum wire just outside one leg of the carbon and with its plane perpendicular to the plane of the horse-shoe.

The aluminium plate was .5 centims. long and 1 centim. wide, and distant from the nearest leg of the carbon about .5 centim. This lamp therefore differed from lamp No. 4 in having the plate outside the carbon loop rather than between the legs. It may be noticed that in this lamp the current here obtained by joining the positive lamp electrode to

the plate through a galvanometer was slightly greater when the leg nearest the plate was *negative* than when it was the positive leg, whereas in the case of lamp No. 2 it is just the reverse. This lamp exhibited also the same effect as lamp No. 4, in that the current flowing between electrode and plate is very liable to "jump" from one value to another even when the lamp is kept at constant volts. The following tabular result of the observations shows this. This lamp is called Lamp No. 6 and was a 50-volt horse-shoe carbon lamp, taking 1.33 amperes of current at a working electromotive force of 50 volts.

[fol. 3053] TABLE No. 11.—*Lamp No. 6, milamperometer*

Table showing the potential-difference between the positive electrode of the lamp and the aluminium plate, and the current in milliamperes flowing through a galvanometer connecting them. Vacuum good.

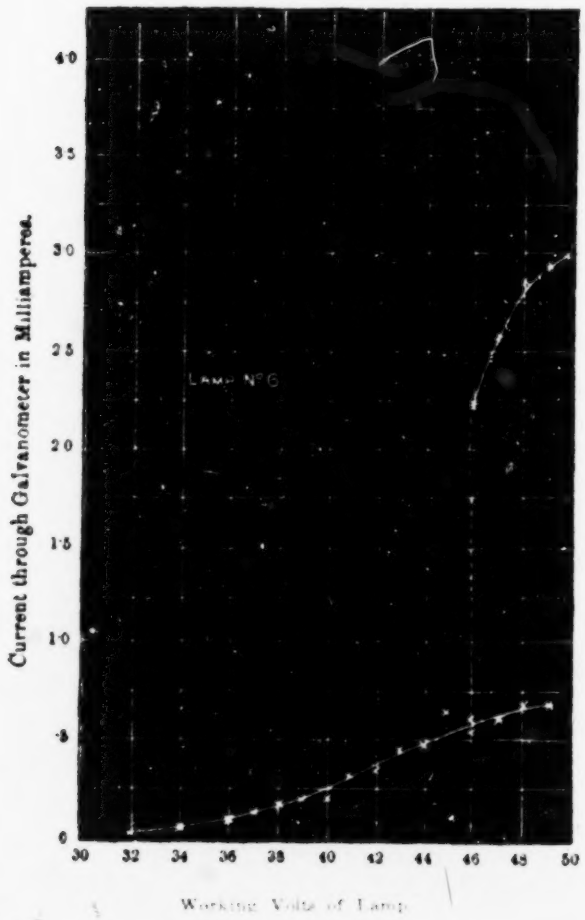
The results in Table No. 11 are plotted in curve No. 5.

[fol. 3054] This table shows that when the lamp is kept at a constant voltage the current through the galvanometer jumps from one value to another. The fluctuation of the current takes place when the negative leg of the carbon is the one farthest from the plate. When the leg adjacent to the aluminium plate is the negative one then the current is steady at any definite voltage of the lamp.

§ 15. From the above experiments it is clear that the current obtained when a galvanometer is connected between a

metallic plate and the positive electrode of the lamp is greater in proportion as the collecting-plate is larger and in proportion as it is brought into close proximity to the base

TABLE No. 11.—*Curve no. 5*



of the negative leg of the carbon. Also that a plate so placed is brought down to the potential of the negative electrode. It seemed desirable to see how far the removal of the collecting-plate to a great distance from the negative leg would influence these results, and experiments were accordingly tried with a tube of the form shown in fig. 11.

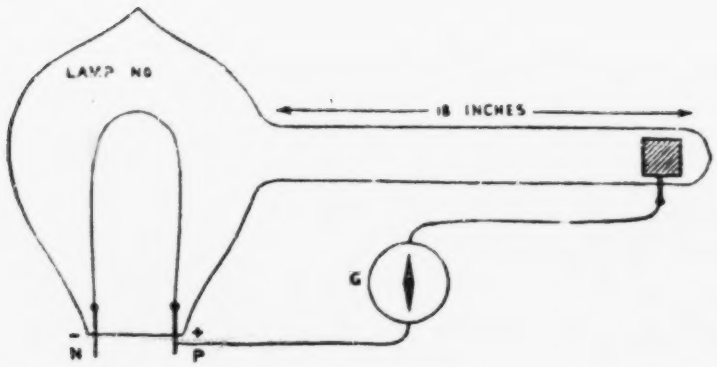


FIG. 11

Experiment 12.—In this case a glass tube about eighteen inches long and three-quarters of an inch in diameter was attached to a lamp bulb. The end of the glass tube farthest from the bulb was closed and an aluminium plate welded to a platinum wire was sealed in near this closed end. The plate had a length of about 3 centimetres and a width of about 1 centimetre. The tube formed an extension of the bulb space, and accordingly this arrangement formed a device by which a metal plate could be removed to a distance of some eighteen inches from the incandescent conductor contained in the bulb. On placing this lamp on a circuit and bringing the carbon to normal incandescence and connecting the terminals of the Elliott galvanometer respectively to the aluminium plate and the positive electrode of the lamp, a very small current was found to be passing through it, not, however, exceeding one ten-thousandth of a milliampere. When the galvanometer was joined in between the aluminium plate and the negative leg of the carbon no current whatever could be detected with this galvanometer, which was sufficiently sensitive to show one hundred-thousandth of a milliampere. We thus find that the removal of [fol.3055] the plate to a distance of some eighteen inches from the incandescent conductors practically extinguishes the phenomenon.

Experiment 13.—Another similar bulb was provided having a side tube blown on it of half the length, viz. about 9 inches long. At the end of this tube was placed a small

aluminium plate as before, and the tube was bent up about the middle at right angles (see fig. 12). When the carbon conductor in the bulb, which was that of an ordinary 50-volt 16 candlepower lamp, was rendered incandescent by being connected to a circuit of appropriate electromotive force, and the Elliott galvanometer connected in between the aluminium plate and the positive electrode of the lamp, a current of not more than about one twenty-thousandths of a milliampere was detected. The fact that the "Edison effect" was extinguished when the collecting-plate was placed at the extremity of an elbow-tube was first observed and recorded by Mr. Preece.

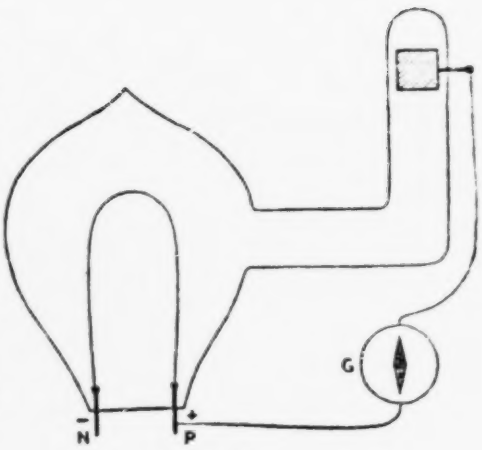

FIG. 12.

§ 16. The effect of position and size of the plate having been examined, the next step which naturally suggested

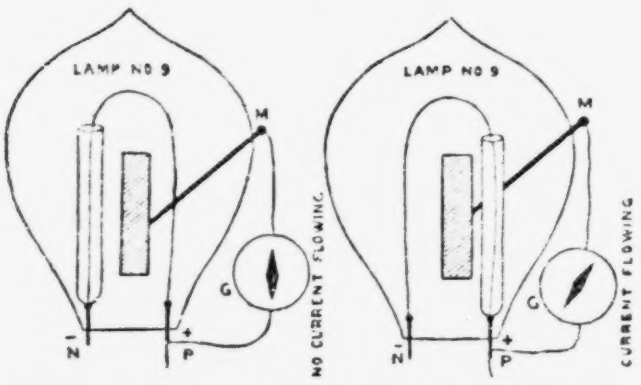

FIG. 13.

itself was to determine the effect of the different portions of the incandescent conductor in the production of it.

Experiment 14.—A lamp like No. 4 was provided, but in which one leg of the carboa was enclosed in a glass tube of the size of a quill. The glass tube was sealed on to the platinum wire and extended nearly up to the bend of the

carbon (see fig. 13). This lamp, called No. 9, was placed [fol. 3056] on the circuit in such a manner that the shielded leg was the *positive* leg, and a series of observations taken as usual of the current flowing through the milamperemeter when connected between the middle plate, placed between the carbon legs, and the positive electrode of the lamp. The results are as tabulated below in Table No. 12. The lamp took 1.25 ampere of current at a working electromotive force of 42 volts.

TABLE No. 12.—*Lamp No. 9, milamperometer*

Table showing the potential difference between the middle plate and positive electrode of the lamp, and the current flowing through a galvanometer connecting them, when the *positive* leg of the carbon is shielded in a glass tube.

Working volts of the lamp	Potential-difference of middle plate and positive electrode in volts	Milliampere current through galvanometer	Working volts of the lamp	Potential-difference of middle plate and positive electrode in volts	Milliampere current through galvanometer
39	0·2	0·032	45	6·9	0·936
38	3	048	46	7·5	1·19
40	95	12	47	9·7	1·53
41	1·2	19	48	12·4	1·96
42	1·8	29	49	15·1	2·39
43	3·1	49	50	19·1	3·03
44	4·2	66	51	23·1	3·66

So far the results are quite normal, and if the results in the above Table No. 12 are compared with those in Table 2 for a similarly constructed lamp with no tubular shield, we find that the magnitude of the current flowing from the positive electrode to the middle plate is in the two cases very much the same. The lamp No. 9 was then placed on the circuit in such a manner that the leg shielded by the glass tube was the *negative* leg, and a similar series of observations of the current between the positive leg (now the uncovered leg) and the middle plate was made. The results were as follows in Table No. 13:—

TABLES No. 12 AND 13. *Curve No. 6*

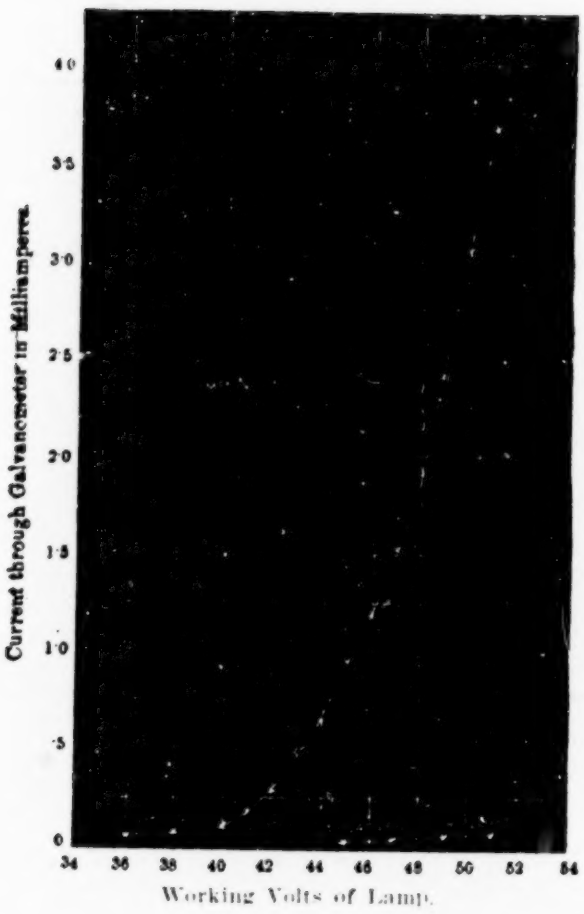

TABLE No. 13.—*Lamp No. 9. Milliampere-meter*

Table showing the potential-difference between the middle plate and positive electrode, and the current flowing through a galvanometer connecting them, when the *negative* leg of the carbon is shielded in a glass tube.

Working volts of the lamp	Potential-difference of middle plate and positive electrode in volts	Milliampere current through galvanometer
45	10	016
47	15	024
49	25	039
51	30	044

On comparing the results in Table No. 13 and the previous one No. 12 we see what an immense reduction in the [fol. 3057] current flowing between the positive electrode and the middle plate is produced by shielding the *negative* leg. Hence the action in virtue of which the current is produced is greatly interfered with by enclosing or covering up the negative leg of the carbon. In this particular case at 51 volts the current between the positive electrode of the lamp and the middle plate when the *negative* leg is covered up is only 1·83 of that which it is when the *positive* leg is covered up. The results in Tables Nos. 12 and 13 are plotted together in Curve No. 6.

17. The question remained to be settled whether the nature of the tubular screen in any way affected the results, and the glass tube was accordingly replaced by a metal (aluminium) tube and a lamp (No. 10) taken in which one of the carbon legs (see fig. 14) was surrounded by an aluminium cylinder extending nearly the whole length of the leg, and also a middle plate of aluminium was placed between the legs. Both the plate and the cylinder were held on platinum wires sealed through the glass. The lamp took 1.25 amperes of current at 41.5 volts.

[fol. 3058] *Experiment 15.*—The lamp was placed on a circuit so that the leg shielded by the aluminium cylinder was the *positive* leg. The milamperemeter was then connected between the positive electrode of the lamp and the middle plate, and the usual measurements made. It was found that the current "jumped" a good deal, and that high and low values of the galvanometer current occurred, even when the terminal voltage of the lamp was kept perfectly constant.

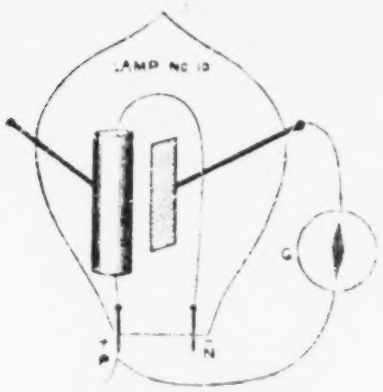

Fig. 14

The lamp was then reversed on the circuit so that the shielded leg was the *negative* one, all other arrangements remaining the same. The current now between the positive electrode and the middle plate was practically zero, at any rate too small to be measured with this galvanometer. Hence we see that shielding the negative leg, whether by glass or

a metallic cylinder, entirely cuts off the production of a current between the positive lamp electrode and the middle plate.

18. *Experiment 16.*—Another series of experiments was made with the lamp No. 10 in which the galvanometer was connected between the positive electrode of the lamp and the aluminium cylinder (see fig. 15), the leg inside the cylinder being either the positive *or* the negative leg. In this case the middle plate remained unused and insulated

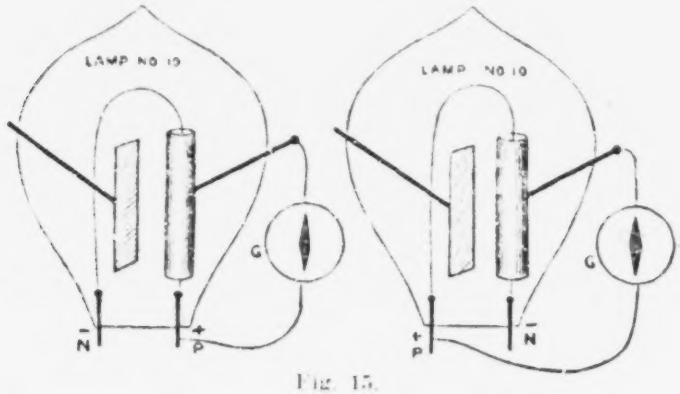

Fig. 15.

and acted as a shield between the cylinder and the carbon leg which was not contained in the cylinder.

It was found that when the cylinder surrounds the negative leg and its surface is, therefore, as much exposed to it as possible the current is a maximum, but that when it includes the positive leg the current is greatly diminished, both by reason of the fact that it opposes less surface to the negative leg, and also because the middle plate acts as a shield between it and the negative leg of the carbon.

[fol. 3059] 19. *Experiment 17.* In order finally to demonstrate that the negative leg of the carbon loop was the chief active agent in this production of a current between the middle plate and the positive electrode, a lamp like No. 4 was taken having a metal middle plate between the legs, and this middle plate had attached to it a mica screen (see fig. 16) a little larger than the plate, and so fixed by a loose rivet that it could be shaken in front of the plate so as to shield one side of it, or shaken on one side so as to fully expose the plate. This device was in fact a removable shield attached to one surface of the metal middle plate,

and when placed up against it, it shielded one surface from, and when jerked on one side it exposed that surface to, the carbon leg opposite to that surface. This lamp (called No. 5) was set on the circuit in the first place so that the leg of the carbon horse shoe opposite to the mica-shielded side of the middle plate was the *positive* leg. If the carbon was brought up to an incandescence corresponding to about 3.5 or 4 watts per candlepower and the galvanometer connected between the positive electrode and the middle plate, then it was found that the effect on the galvanometer current which was produced by the interposition or withdrawal of the screen of mica between the positive leg and the plate was not very great. It reduced the current through the galvanometer from about .44 milliampere to .38 milliampere. If, however, the current flowing through the lamp carbon is reversed in direction so that the mica screen is interposed on that side of the middle metal plate which faces the *negative* leg, the result is very different. When the screen is down, the current flowing through the galvanometer from the positive electrode to the middle plate being as before .44 milliampere, the interposition of the mica screen on the side of the plate facing the negative leg reduced the current at once to zero. We find therefore, that the interposition of a mica screen between the middle plate and the negative leg reduces to zero the current flowing between the positive lamp electrode and the middle plate. As in all other lamps with a middle plate set exactly between the legs, the current through the galvanometer joining the middle plate and positive electrode is very liable to "jump" from a low to a higher value or *vice versâ*. When the current has its higher value corresponding to any given voltage on the lamp terminals, the effect of screening is less marked, and although the interposition of the mica screen on the side facing the negative leg has an effect of reducing the current flowing through

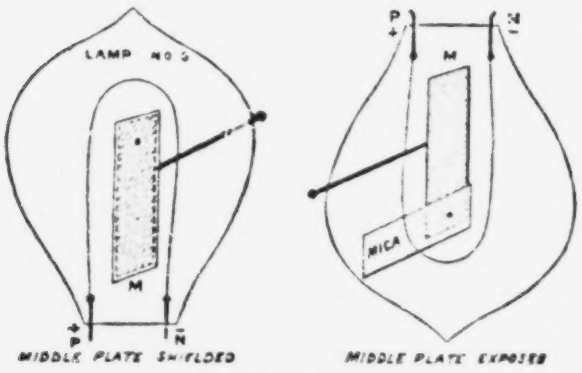

FIG. 16

[fol. 3060] the galvanometer connected between the middle plate and positive electrode, it is not by any means reduced to zero.

§ 20. The foregoing experiments afford proof that the production of the current through a galvanometer joined between the positive electrode of the lamp and a metal plate placed somewhere in the vacuous bulb, is an effect due chiefly to the *negative* leg of the carbon, and that shielding the negative leg by enclosing it in a glass or metal tube, or covering with a mica screen that surface of the plate which is exposed to the negative leg, either quite prevents or greatly reduces the production of this current. The experiments also have shown that the magnitude of the current flowing through the galvanometer is increased by bringing the plate near to the base of the negative leg, or, better still, making the metal plate in the form of a cylinder and making this cylinder surround the *negative* leg near its base; and correspondingly it is diminished by removing it from the negative leg to a considerable distance, or by shielding this collecting-plate from the radiation from the negative leg of the carbon. The experiments with the condenser have also given evidence that when an insulated metal plate is sealed into a lamp, this plate is brought down either instantly or in a very short period of time to the potential of the *negative* leg near its base or to that of the *negative electrode* of the lamp. In looking for an explanation of these facts we are assisted by our previous knowledge that in carbon incandescence lamps, when working at an efficiency equivalent to 3 to 4 watts per candle-power, there is a gradual loss of carbon from all parts of the conductor. We know also that the carbon molecules which are projected from the conductor are thrown off into a space so highly vacuous that their mean free path is of a length comparable with, or greater than that of the dimensions of the glass bulb. The existence of molecular shadows in incandescence lamps[3] affords evidence that from intensely heated portions of the carbon conductor carbon molecules are projected in straight lines and move freely forward until they impinge against the glass. Commercial experience informs us that at and above a temperature corresponding to 3 watts per candle-power this loss of carbon becomes

[3] See J. A. Fleming, "Philosophical Magazine," August 1885, p. 141, vol. XIV.

very rapid and thins away the filament in one place, or generally reduces the diameter of the carbon conductor. Hence we have every reason to believe that when in a normal state of incandescence the carbon conductor in a lamp is throwing off in all directions carbon molecules, and that in the vacuum usually obtained the mean free path of these projected molecules is comparable with the dimensions of the vessel containing the conductor. The whole of the experiments which are detailed here seem to be capable of consistent interpretation if we may justifiably make the hypothesis that these carbon molecules or atoms so projected from the conductor when intensely heated by the current flowing through it are all *negatively* charged. Some of the observed [fol. 3061] facts seem to point to the conclusion that the molecules projected from the incandescent conductor, whether they are portions of the conductor itself or molecules of the residual gases, respectively carry away negative charges proportional in magnitude to the potential of the conductor at the point from which they are thrown off. They may, therefore, be looked upon as condensers of small but definite electrostatic capacity charged to the potential (negative) of that part of the incandescent conductor at which they separate from it. We have then in addition to explain how it comes to pass that there are few or no projected molecules charged positively. Two suggestions may be made on this point: either the radiation of matter is wholly confined to that half of the conductor at a negative potential or the incandescent carbon molecule thrown off from the heated conductor cannot retain a positive charge. There is much to lead to the conclusion that from *all parts* of the incandescent carbon conductor there is a constant radiation of matter carrying a negative electric charge. The nearer down to the negative electrode of the carbon we select our point of observation the greater is this molecular charge found to be. It will be convenient to denote this conveyance of electric charge by moving charged molecules by the term *molecular electric*

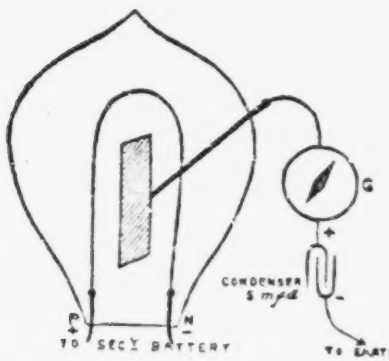

Fig. 1.

vection. We can then state the hypothesis thus—from all portions of the negative leg of the carbon loop a process of molecular electrovection is going on when the conductor is incandescent, the molecular charge being negative, and equal in potential to that of the point on the conductor from which it is projected.

21. On the assumption that a molecular shower of negatively charged atoms was being projected against the middle plate when the conductor of the lamp was incandescent it was considered probable that a positively charged conductor connected to the middle plate would be discharged, and this was found to be the case.

Experiment 18.—A lamp of the form of No. 4, having a middle metal plate placed between the carbon legs, had its middle plate connected to one terminal of the Elliott galvanometer. The other terminal of the galvanometer was connected to one terminal of a condenser of 5 microfarads capacity. The other terminal of the condenser was connected by a wire to the gas pipes of the laboratory. The lamp was actuated by secondary batteries (see fig. 17) not very well insulated. If the condenser was charged to a potential of 50 volts so that the plate next the galvanometer was *positively* charged, then this positive charge was *instantly discharged* when the carbon was rendered incandescent. If, however, the plate of the condenser in connexion with the middle plate through the galvanometer was [fol. 3062] charged *negatively* the condenser was not discharged when the lamp was illuminated by rendering its carbon incandescent. It is a very striking experiment to see a condenser charged with this amount (250 microcoulombs) of electricity instantly discharged when its positive coating is brought into connexion with the middle plate of such a lamp. The discharge may be brought about either by joining up the positive side of the condenser to the middle plate first, and then rendering the carbon of the lamp incandescent by switching on the lamp, or the lamp may be first of all illuminated and then the junction of the condenser effected. In both cases the middle plate when positively electrified is instantly discharged.

It was found that if the lamp carbon is rendered incandescent by a highly insulated secondary battery, then in order to produce the discharge, the plate of the condenser not in connexion with the middle plate, and which is *negatively* charged, must be somewhere connected with the bat-

tery circuit. It does not matter, however, whether the wire from the negative side of the condenser is in connexion with the positive or the negative pole of the secondary battery actuating the lamp; all that is necessary is that the negative side of the condenser should be in conducting connexion with the circuit of the incandescent carbon. The experiment may be interpreted by considering that this negative charge of the condenser can escape out of the incandescent conductor and discharge across the highly vacuous space to the positively electrified cool middle metal plate; but that a positive charge cannot be discharged out of the hot conductor, or, which amounts to the same thing, a negative charge cannot discharge across from the cool metal plate to the incandescent carbon which is positively charged. We have then a unilateral conductivity exhibited by this highly vacuous space bounded by two electrodes one of which is incandescent and the other of which is cold. Negative electricity is discharged at once out of the hot surface but not out of the cold, and a negative discharge can take place from hot to cold but not *vice versâ*. When the discharge of a charged condenser is effected by connecting the positive plate, through a galvanometer, with a metal plate sealed into the lamp and the negative plate with the lamp circuit, and then switching on the lamp, there is a curious instant of delay before the discharge begins. When the metal plate is placed very near the negative leg of the carbon the discharge of the condenser is complete in one instant. This — the case when a lamp of the type No. 4 (fig. 18) is used. If, however, we employ a lamp of the type No. 2 (fig. 10), in which the metal plate is at some distance from the negative leg of the carbon, the discharge of the condenser is long drawn out and the electric charge in it is as it were tapped off slowly and not in one short sharp discharge.

Moreover this effect of discharging a condenser takes place only when the carbon is above a fair red heat. At brilliant incandescence and when the carbon is above a temperature corresponding to 3 watts per candle-power, the discharging power of a lamp of the type of No. 4 is very great. A condenser of 10 or 20 microfarads capacity [fol. 3063] charged to 50 volts is discharged instantly if its positive plate is connected to the metal plate placed not far from the negative end of the incandescent carbon conductor.

The foregoing results were confirmed with lamps of other types. Using, for instance, a lamp like No. 6 with the aluminum plate placed outside the carbon horse-shoe and near the leg, the same discharging power for positive electricity was found. It was not dependent on the direction of the current through the lamp carbon, although it seemed a little more vigorous when the leg nearest the plate was the negative leg. As above observed, the rate of discharge was much reduced when employing a lamp having the metal plate placed edgeways on to the carbon and some way from it, as, for instance, when employing a lamp of the form of No. 2.

§ 22. *Experiment 19.*—A series of experiments was in this case also tried to determine the effect of shielding the negatives leg of the carbon. The lamp No. 9 was employed, in which one leg of the carbon was enclosed in a glass tube connecting the positive plate of a charged condenser through a galvanometer with the middle plate of the lamp, and the negative plate of the condenser somewhere to the battery circuit; it was found that when the shielded leg of the carbon was the positive leg the condenser was discharged as before. If, however, the shielded leg or enclosed in the glass tube was made the negative leg, which could be done by reversing the current through the carbon conductor, then the condenser was not discharged when its positive plate was connected with the middle plate.

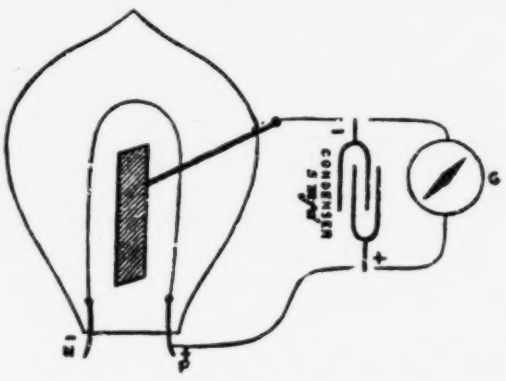

FIG. 18.

The same fact was less perfectly exhibited by employing the lamp with the middle plate having a removable mica shield on one side. We are thus able to assure ourselves that the active agent in producing this discharging effect upon a positively charged body connected to the middle plate is the negative leg of the carbon conductor. The experiments were varied in many ways, but all pointed to the conclusion that if a charged condenser is connected to two terminals, one of which is a metal plate and the other a

carbon conductor, both enclosed in a high vacuum but yet separated from each other by an inch or so of distance, the condenser is discharged instantly when the carbon terminal is rendered highly incandescent, provided that the negative plate of the condenser is in connexion with it.

23. If the condenser is left in contact with the middle plate under some circumstances, not only is it discharged if previously charged but is charged again in an opposite direction.

[Vol. 3064] *Experiment 20.* A condenser of 5 microfarads capacity perfectly discharged has its poles or terminals connected for one instant, one with the middle plate of No. 4 lamp and the other with the positive electrode of the lamp (see fig. 18). On removing it and testing it with the galvanometer G it is found that the condenser plate in connexion with the middle plate of the lamp has received a negative charge and the other plate of the condenser a positive charge.

If, however, the condenser is connected between the negative electrode of the lamp and the metal middle plate of the lamp, on insulating and testing it we find it has not the slightest charge.

It is very astonishing to see how instantly a condenser of very large capacity is charged when one pole of the condenser is connected to the middle plate and the other to the positive electrode of the lamp.

24. In considering the behaviour of the heated carbon electrode and the cool metal plate in their respective powers of discharging the positive or negative charge of the condenser, it seemed that the fundamental fact was the power of the heated surface to discharge negative electricity out of itself. Hence arose the question, how far the observed facts would be modified if the middle metal plate itself could be also heated. One way by which this might have been done would have been to have rendered this plate incandescent by heating it by radiant heat concentrated by means of a powerful mirror or lens. Some

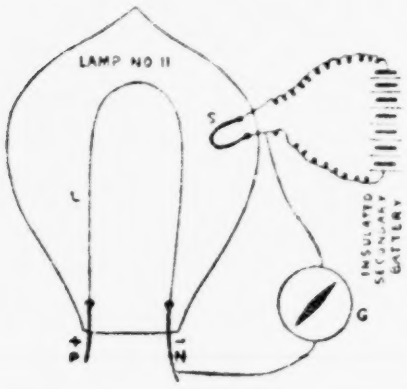

FIG. 19

experiments tried in this way were not satisfactory, and consequently a method was adopted in which a middle plate of carbon could be rendered incandescent electrically.

Experiment 21.—A vacuum tube was provided with two carbon conductors (see fig. 19), one the ordinary carbon filament L of a 50 volt lamp, and the other the small carbon S of a 4 volt lamp. The smaller carbon was sealed in the usual way through the glass and placed so as to stand symmetrically between the legs of the larger carbon loop.

The smaller carbon could be rendered incandescent by an insulated battery of fifteen secondary cells, appropriate resistance being introduced. The larger carbon also could be rendered incandescent by the proper electromotive force. If the smaller carbon was kept cold and employed simply as a third electrode or middle plate, all the phenomena previously described as happening with metal middle plates of aluminum or platinum took place. If the small (cold) carbon loop is connected through a galvanometer with the positive electrode of the larger carbon loop when this last is rendered incandescent by a current, we find as usual a [fol. 3065] current of a few milliamperes passing through the galvanometer from the positive electrode of the larger carbon to the small carbon. If the small carbon (still cold) is connected through the galvanometer to the negative electrode of the larger carbon, we get no current. This is the normal effect, and it is the same for a cold carbon conductor used as a middle plate as for a metal middle plate.

Experiment 22.—The next experiment consisted in making this small carbon incandescent by an insulated secondary battery, appropriate resistance being inserted so that the carbon was brought to the normal condition of temperature as indicated by its incandescence. When this was done the galvanometer was inserted between the positive electrode of the large carbon loop and one of the electrodes of the small carbon loop. A current was obtained as before. On connecting the galvanometer between the *negative* elec-

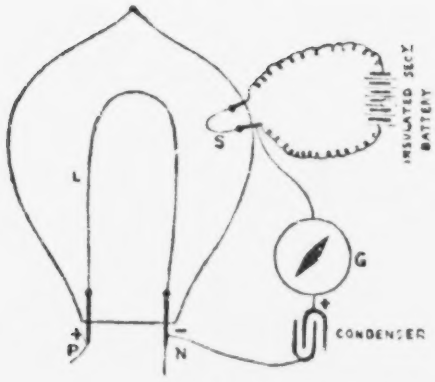

FIG. 20.

trode of the large carbon loop and one of the electrodes of the small carbon loop, a current of nearly equal value was now obtained. In this last experiment it was found to be immaterial whether the terminal of the galvanometer was joined to the positive or to the negative electrode of the small carbon loop. Hence we find that when the small carbon loop is not incandescent and is used as a middle plate or electrode, it is brought down together with the insulated battery attached to it to the same potential as the negative end of the large incandescent carbon, and we get as usual a current through a galvanometer connected between the positive electrode of the large incandescent carbon and any point on the small cold carbon, and no current between the negative electrode of the large hot carbon and the small cold one. On rendering the smaller carbon loop incandescent this is all changed. The smaller carbon, now hot, is not brought down to the potential of the negative ends of the larger carbon, and we get a current through a galvanometer connected between either positive or negative electrode of the large hot carbon and any point on the circuit of the smaller equally hot carbon.

25. *Experiment 23.*—With this same vacuum tube having double carbons, further experiments were performed on the discharging power of the hot and cold electrodes for positive and negative electricity. The two carbons could be rendered incandescent either simultaneously or singly by two sets of insulated secondary batteries attached to each respectively. For the sake of distinction we shall speak of the large carbon loop in this bulb as the L loop and the smaller one as the S loop. A condenser of 5 microfarads capacity (see fig. 20) was employed, which was charged to a potential of about 50 volts. When the positive plate of [fol. 3066] this charged condenser was attached to the carbon L and the negative side to the carbon S, then on making L incandescent by its own insulated battery and keeping S

cold, the condenser was found not to be discharged when insulated and tested by a galvanometer. If, however, the same charged condenser was connected in the same way to the two carbons and the carbon S, to which the negative side of the condenser was attached, was made incandescent, the condenser was instantly discharged. If the direction of the charging of the condenser was reversed the same rule was found to hold good. The condenser was discharged if the *negatively* charged plate of the condenser was connected to the *incandescent* carbon loop, but not if it was connected to the cold carbon loop. Beginning with the condenser charged and connecting it in between the two carbon loops, neither of them being incandescent, then the condenser was discharged instantly if that loop to which the *negatively* charged side of the condenser was attached was rendered incandescent, but not discharged if the loop to which the positive side of the condenser was connected was rendered incandescent. If both loops were rendered incandescent simultaneously the condenser in any case was discharged, but apparently at an accelerated rate. These experiments show again that if two carbon electrodes are sealed into a high vacuum, negative electricity escapes very freely out of either electrode if it is rendered incandescent, but that the escape or discharge of positive electricity is not in the same way facilitated by heating the positive electrode. Accordingly a highly vacuous space bounded by two carbon electrodes separated by a distance less than the mean free path of the gaseous molecule at that pressure, presents a unilateral conductivity when one of these electrodes is cold and the other highly incandescent. For if the hot electrode is connected to a negatively charged body and the cold electrode to a positively charged body, discharge takes place across the vacuous space, but if the charges are reversed then no discharge takes place. The negative charge can escape from the heated electrode but not from the cold one.

§ 26. *Experiment 24.*—The question of the apparent unilateral conductivity of the vacuous space bounded by a hot and a cold electrode was then further examined by the aid of the lamp No. 6 formerly used.

In this lamp an aluminum plate is sealed into the vacuum and placed just outside the carbon horse-shoe. If a sensitive galvanometer (the high resistance *Elliott* galvanometer) is joined up between the metal plate and the negative

electrode of the lamp, then, as in other cases when the lamp is in action, no current of a magnitude much greater than .0001 of a milliampere is detected. If a single Clark standard cell is inserted in the galvanometer circuit (see fig. 21) with its negative pole attached to the middle plate and its positive pole to the galvanometer terminal, the current is barely if at all increased. In this case the negative pole of the Clark cell is in connexion with a cold metal electrode and the *positive* pole is in connexion through the galvanometer with the incandescent carbon electrode, and under these circumstances the galvanometer detects no current [fol. 3967] flowing. The position of the Clark cell is now reversed, and it is joined up so that its positive pole is in connexion with the middle plate and its *negative* pole in connexion, through the galvanometer, with the incandescent carbon electrode. It is then found that a considerable current of some few milliamperes in magnitude is flowing through the galvanometer. The direction of this current in the ordinary way of speaking is *from* the negative electrode of the lamp through the galvanometer *to* the metal plate sealed into the bulb. We thus find that a negative current of electricity can be made to flow across the vacuous space between the incandescent carbon and the metal plate *from* the hot carbon *to* the cooler metal plate, but not in the reverse direction. The space presents an apparently unilateral conductivity.

27. *Experiment 25.*—The same experiment was repeated, only using instead of a Clark cell an insulated sec-

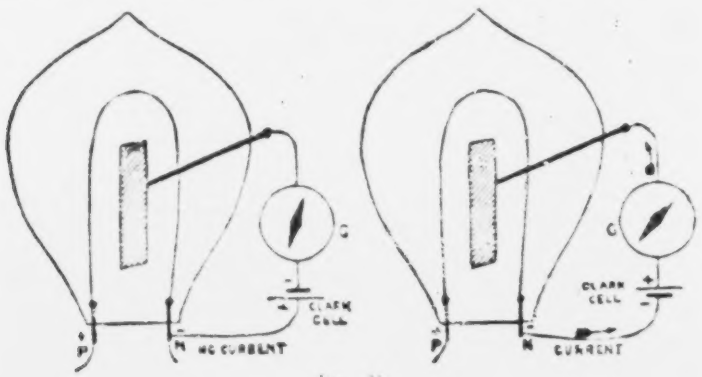

FIG. 21

ondary battery of 25 small cells. When the secondary battery (see fig. 21) was connected with its negative pole to the metal plate and its positive pole through the galvanometer

to the negative electrode of the carbon, no current greater than that found with the Clark cell similarly arranged was found; but if the secondary battery was reversed and joined up with its positive pole to the middle plate and its negative pole through the galvanometer to the negative electrode of the incandescent carbon, then so strong a current flowed through the galvanometer that it could not be measured without shunting down the galvanometer considerably. The same experiments were repeated with the lamps having the zigzag wire as a metal plate, No. 7, and the same general results obtained. These experiments therefore show that in a circuit which consists partly of a galvanometer-wire and partly of a highly vacuous space bounded by two electrodes—one a metal plate and the other an incandescent carbon surface—the insertion of an electromotive force in one direction can produce a very sensible current, but that if the electromotive force is reversed then no current flows. The direction of the electromotive force must be such as to urge negative electricity from the hot surface to the cold across the vacuous space.

[fol. 3068] 28. *Experiment 29.*—In order to make use of different parts of the incandescent conductor as the electrode opposed to the metal plate, recourse was had to the lamp No. 3, with metal (aluminum) cylinders embracing without touching the carbon at two different places. These

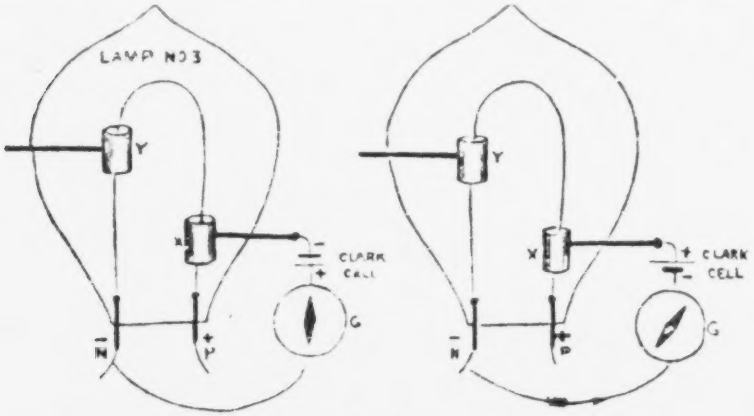

FIG. 22

cylinders, as before, we will call X and Y (see fig. 22). Cylinder X was the one near the base of the positive leg of the carbon, and cylinder Y was the one near the top of the negative leg.

When the galvanometer was connected between the negative electrode of the lamp and the cylinder X surrounding the lower part of the positive leg, no perceptible current was found to be passing when the carbon was rendered incandescent. On inserting a single Clark cell in series with the galvanometer so that the negative pole of the cell was in connexion with the cylinder X and the positive pole of the cell through the galvanometer in connexion with the negative electrode of the lamp, hardly any perceptible current was found to be passing (see fig. 22). The Clark cell was then reversed, connecting the positive pole of the cell to the cylinder X and the negative pole through the galvanometer to the negative electrode of the lamp. On bringing the lamp into action, a considerable current of several milliamperes was found to be passing in such a direction that a current of positive electricity was flowing across the vacuous space from the metal cylinder to the hot carbon, or a negative current from the hot carbon to the cooler metal cylinder. On switching off the lamp, there was a curious "kick" or "throw" of the galvanometer, indicating a sudden rush of current in the same direction as the steady current which the cell had been sending. These effects occurred also when the cylinder Y was employed, and the galvanometer with or without the cell in series joined in between the negative electrode of the lamp and the cylinder Y embracing the top part of the negative leg of the carbon (see fig. 22); but in the last case the steady current sent by the cell across the vacuous space between the cylinder and the hot carbon was only about a quarter as great in magnitude as when the cylinder X was employed. There was the same kind of [fol. 3069] "kick" of the galvanometer on breaking the lamp circuit. These experiments evidently show that the highly vacuous space between the hot carbon traversed by its own current, which rendered it incandescent, and the insulated cylinder possessed a sort of unilateral conductivity, negative electricity from a separate source of small electromotive force being able to be forced through it from the hot carbon surface to the cooler metal surface, but not in an opposite direction.

29. In the above-recorded experiments the carbon conductor was rendered incandescent by a unidirectional or continuous current in a highly perfect vacuum. In seeking for an hypothesis to connect them together, it became essen-

tial to ascertain how the effects would be modified if the vacuum was imperfect and if the current was alternating instead of continuous.

Experiment 27.—The fundamental experiment was therefore repeated with the normal type of lamp (No. 4), having a middle metal plate placed symmetrically between the legs of the carbon. A lamp of this type was set in action by an alternating current of suitable strength and of which the frequency was some 80 to 100 per second. On connecting the milamperemeter between *either* of the electrodes of the lamp and the middle plate, a *continuous* electric current was found flowing through the galvanometer. The direction of this current was such that positive electricity was found to flow from either lamp terminal to the middle plate of the lamp. In other words, a continuous current of negative electricity flowed out of the middle plate to one or other of the two terminals of the lamp, viz. to that terminal to which the other extremity of the galvanometer was joined. Hence, since in this case each leg of the carbon becomes in rapid succession positive *and* negative when the lamp is operated with an alternating current, the unilateral effect observed of a current flowing between the middle plate and the positive leg, when the current through the carbon is a continuous current, is here found to exist equally between the middle plate and *both* terminals of the lamp. This is only what might have been expected. The potential of the middle plate is then not the same as that of the base of either leg of the carbon, but something between the two depending upon the position of the plate.

§ 30. *Experiment 28.*—The effect of lowering the vacuum was also the subject of experiment. In a lamp with a highly perfect vacuum no current greater than about .0001 milliampere is observed when a very sensitive high-resistance galvanometer is joined up between the negative electrode of the carbon and the insulated middle plate, and, as we have seen the experiments with the electrostatic voltmeter showed that the plate was brought down under these circumstances to the potential of the base of the negative leg of the carbon. If, instead of employing a very perfect vacuum, a bad one is produced by imperfectly exhausting the lamp, then it is found that under these conditions the Elliott galvanometer indicates a not inconsiderable current of something approaching to a milliampere when joined in be-

tween the negative electrode of the lamp and the middle [fol. 3070] plate. Hence, when the vacuum is imperfect the equality in potential between the middle plate and the negative electrode is not maintained.

The direction of the current in this last case is such as to show that negative electricity is flowing through the galvanometer from the negative electrode of the lamp to the middle plate. In other words, negative charge is carried over from the plate to the positive leg of the carbon across the imperfectly vacuous space; and the means by which this is effected is the residual air. This seems to afford proof that the normal effect of the molecular electrovection of negative electricity from the negative leg is due to carbon molecules, and that the presence of residual air exhibits itself, when present beyond a certain amount, in producing an effect which the carbon molecular electrovection cannot produce.

31. *Experiment 29.*—It seemed very desirable to ascertain if the effect of molecular electrovection exists in the case of an incandescent platinum wire rendered vividly incandescent in a highly perfect vacuum. A bulb was accordingly constructed similar in every way to lamp No. 4, but having a platinum wire horse-shoe conductor and a platinum middle plate. When this wire was rendered highly incandescent by a continuous current, a sensitive galvanometer (the high resistance Elliott) showed a current of about one five-thousandth of a milliampere when connected between the positive electrode of the incandescent wire and the middle plate, but little or no current when connected between the negative electrode and the middle plate. This molecular *electrovection* current was thus very much less in magnitude than that observed in the case of the carbon filament lamps, but it is in the *same direction*. We are, however, enabled to state that at a condition of vivid incandescence just short of fusion a platinum wire *in vacuo* exhibits the same effects as a carbon filament, and that it can disturb the electrical condition of an insulated metal plate near it sealed into the same vacuum and tends to bring it down towards the potential of the negative end of that platinum wire.

On the hypothesis that all these effects are due to a scattering of negatively charged molecules from the incandescent conductor, we must affirm that the same process goes on in a platinum wire rendered incandescent in a vacuum,

only that the radiation of matter is far greater in the case of the incandescent carbon than it is in the case of the incandescent platinum.

§ 33. If a lamp is selected having an insulated plate fixed between the legs of the carbon filament it is found that under certain conditions the electric conductivity of the vacuous space between the plate and the negative leg is much affected by the presence of a magnetic field. If a galvanometer, preferably a movable coil galvanometer, having a resistance of about 500 or 600 ohms, is connected between the middle plate and the negative leg it will show but little current passing when the lamp is incandescent at normal temperature. If the volts on the lamp terminal are raised so that the filament is brought into a state of incandescence corresponding to about 2.5 or 3 watts per candle, then the [fol. 3071] galvanometer will show a small current passing through it. If then a horse-shoe magnet is held so as to create a magnetic field the direction of which is across the space between the plate and the negative leg, the current indicated by the galvanometer immediately decreases considerably. This happens irrespective of the direction of the field so long as it is across the direction of the line joining the negative leg and the middle plate. This indicates that the presence of this transverse field increases the resistance of the rarefied gas. The galvanometer current responds to the presence of the magnet in a manner which shows that the resistance to the flow of the current through the gas is increased by creating a magnetic field at right angles to the line of the current. The general fact that gaseous resistance is increased by such a transverse magnetic field has been already noted and described by Professor J. J. Thomson. The behaviour of bismuth as regards electrical resistance in a magnetic field is strikingly similar.

The "jumping" of the current from one value to a higher, which has been already mentioned, appears to be due to something equivalent to a sudden change in the resistance of the space between the negative leg and the middle plate when the lamp is in action and at high incandescence. The fact of sending a small current through this space seems to effect a change in the qualities of the rarefied gas as a conductor which makes it conduct better. There are certain after-effects in some cases which are strongly similar to the polarization of electrodes observed in the case of liquid elec-

trolysis, and which seem to point to the validity of the view that gaseous conduction is effected by a similar process.

The experiments also confirm the opinion of Professor J. J. Thomson that gases, or at least certain gases in a rarefied condition, are very good conductors, and they show that the greatest part of the obstacle to conduction through a vacuum tube is at the electrodes and may be largely removed by heating the kathode to incandescence.

Discussion

Prof. S. P. Thompson said he would like to have some information as to the state of exhaustion of the lamps; whether this was such as is found in ordinary commercial lamps, or whether it more nearly approached that used by Crookes. A great change in the conductivity, &c., took place at an exhaustion slightly greater than that ordinarily found in incandescent lamps. It would be of interest to vary the size of the kathode, and to investigate whether the magnitude of the effects observed depended on the fall of potential per unit length along the filament. Another point was whether the position of the plate for which the effect was a minimum was the same for all lamps, or whether it changed with the volts and the length of the filament employed. Again, did the minimum occur at a certain fraction of the distance between the positive and negative leads, or, as was the case in some of the phenomena observed by Crookes, at a definite distance from either of the leads? These points might be [fol. 3072] investigated by means of a lamp with a straight filament, where the fall of potential per unit length along the filament could be made the same as with the loop-shaped filament but the fall of potential per unit length in the vacuum would be different. The author's proposed experiment of heating the kathode by concentrating on it the rays of a lamp did not seem to him (Prof. Thompson) to differ materially from Crookes' experiment in which an incandescent wire, heated by a current, was used as the kathode.

Mr. Skinner said that the heating of the kathode by means of a "burning-glass" could easily be carried out.

Mr. Blakesley pointed out that it would be quite possible to produce an increase of the current by means of a magnet.

Mr. Searle said that Prof. J. J. Thomson had shown that a magnet affected the conductivity of a gas.

Prof. Fleming, in his reply, said that no doubt the effects

were largely dependent on the vacuum in the lamps. The lamps employed were exhausted to the ordinary commercial vacuum. Since it was found that the "treating" was more worn off the negative leg of the filament, and that a screen placed between the legs of the filament was more blackened on the side turned towards the negative leg, it would appear that the particles of carbon were shot off from the negative leg, and hence perhaps the charge was carried by these carbon molecules.

Translation of Wehnelt Article

A Wehnelt (Erlangen), in reference to the exit of negative ions from incandescing metallic oxids and phenomena connected therewith.[1]

In a treatise with the same heading in Vol. 14, pp. 425-468 of the Annalen der Physik (1904) I have set forth a series of experiments and measurements which showed that certain metallic oxids, and in fact, especially the oxids of the earth alkali metals in an incandescing state, both under atmospheric pressure and also in a vacuum, emit numerous negative ions. (electrons)

In intimate connection with this quality stands the fact also discovered by me, that the cathode drop in a glimmer charge completely disappears on glowing oxid cathods even under the deepest pressures, provided that the current density (current strength per square centimeter of incandescing oxid surface) remains below a value depending upon the temperature and increasing with this. That current density at which a cathode drop begins to show I have called the limit current density. It attains, under high incandescence of the oxid, values up to three amperes.

I wish today to first bring before you some experiments which explain that which has been said above, and then to show you a practical application of incandescing oxide cathodes.

---

[1] Read in Division 2 on the 21st of Sept. Exhaustive literary references are to be found in Annalen der Physik Vol. 14, p. 425-468, 1904.

Emission of Negative Ions by Incandescing Metallic Oxids. A glass tube R (Fig. 1), exhausted to a moderate extent, contains a brass cylinder C in the axis of which [fol. 3074] there is situated a thin platinum wire D covered with CaO. The wire can be heated to high temperatures by the current of two accumulators A. If I connect the wire D with the one pole, the cylinder C through a galvanometer G with the other pole, of a source of current B, then there only flows a current through the tube if D is connected with the negative pole of B. The experiment shows consequently that only negative ions are emitted from the incandescing oxid.

If I take another tube, which is otherwise exactly similar, but which contains a platinum wire carefully cleaned, and heat the same to the same temperature as previously the wire covered with CaO, then the current is under an equally high negative charge of the wire only exceedingly weak, and in fact, only about 1 1000 of that in the former experiment.

Incandescing Metallic Oxids as Cathodes in Discharge Tubes. The tube R (Fig. 2) contains as cathode K a platinum sheet P covered with CaO which can be electrically heated red hot, and as an anode an iron wire A. The surface of the incandescing metallic oxid cathode amounting to several square centimeters, allows of sending through the tube considerable current strengths, even under deep pressures without there being present a cathode drop.

Since the anode drop constantly amounts to about 20 volts and the drop on the positive cells under strong currents and low pressures, as special measurements have shown, amounts to only one to two volts per centimeter, I can, by using the light conductor of 220 volts potential, send through the tube Fig. 2 currents of several amperes strength. The incandescing oxid cathodes furnish us consequently with a means of investigating the processes in the positive column with any gas whatever and under any pressures however deep, up to very high current strengths. The remarkable brightness of the positive strata under high current strength promises to be serviceable to the spectroanalytical investigation of gas spectra. Quartz windows on [fol. 3075] the tube would also make the ultra violet portion of the light of the strata accessible to investigation.

Weak Cathode Rays: If we exceed the limit current density either by increasing the current strength or decreasing the temperature of the incandescing oxid cathode, then we can impart to the cathode drop any desired value, and consequently produce cathode rays of any desired velocity.

The tube, Fig. 3, contains as cathode K a small platinum sheet P upon which there is located a small speck of calcium oxid.

A brass rod A serves as anode. If the sheet P is electrically brought to a glowing heat and the electrodes A, K, by throwing in a suitable resistance are connected with the light conductor of 220 volts potential, then the entire current goes only through the calcium oxid coating on the cathode sheet P, since here the cathode drop is much lower than on the clean platinum sheet, whereby there proceeds an intensely blue cathode beam of rays from the coating. By changing the temperature of the platinum sheet, there can be imparted to the cathode rays then any desired velocity, and this can then be measured according to well-known methods.

Application of Discharge Tubes with Glowing Metal Oxid Cathodes in Practice. If in an exhausted discharge tube R (Fig. 4)[1] we push one or several metallic electrodes A [fols. 3076-3077] close to the glowing metallic oxid electrode K (platinum sheet P covered with CaO) then the discharge potential, if A is anode and K is cathode, amounts to only about twenty volts. If we reverse the direction of current, so that now A is cathode and K is anode, the discharge potential now amounts to some thousands of volts, since under deep pressures the cathode drop on metals takes on exceedingly high values. If, therefore, we connect the electrodes A and K with an alternating source of current, the potential of which lies below the value which the cathode drop on the metallic electrode A has, then the tube acts as an electric valve, in that it allows to pass through only one phase of the alternating current. The tube (Fig. 4) can consequently serve for the purpose of transforming alternating current into pulsating direct current.

The maximum current strength to be sent through the tube (valve tube) depends as follows, from what has been

[1] The cathode K is assumed to be turned 90° as regards the plane of the picture.

said above, upon the size of the glowing oxid surface. The efficiency of the valve tube depends upon the working potential employed, and increases with this, since the tube up to the strongest allowable current strength, entirely independent of this, absorbs always only 20 volts potential. In applying a working potential of 120 volts alternating current, taking into consideration the consumption of watts for heating of the metal oxid cathode, the efficiency of the valve tube amounted to about 65%.

By using the well-known Graetz system of connection, both phases of the alternating current can be utilized. By using three metallic anodes, we can as with a Hewitt transformer, also transform rotary current into pulsating direct current.

Discussion.

LVIII. *On the Masses of the Ions in Gases at Low Pressures.* *By* J. J. THOMSON, *M.A., F.R.S., Cavendish Professor of Experimental Physics, Cambridge* *.

IN a former paper (Phil. Mag. Oct. 1897) I gave a determination of the value of the ratio of the mass, m, of the ion to its charge, e, in the case of the stream of negative electrification which constitutes the cathode rays. The results of this determination, which are in substantial agreement with those subsequently obtained by Lenard and Kaufmann, show that the value of this ratio is very much less than that of the corresponding ratio in the electrolysis of solutions of acids and salts, and that it is independent of the gas through which the discharge passes and of the nature of the electrodes. In these experiments it was only the value of m/e which was determined, and not the values of m and e separately. It was thus possible that the smallness of the ratio might be due to e being greater than the value of the charge carried by the ion in electrolysis rather than to the mass m being very much smaller. Though there were reasons for thinking that the charge e was not greatly different from the electrolytic one, and that we had here to deal with masses smaller than the atom, yet, as these reasons were somewhat indirect, I desired if possible to get a direct measurement of either m or e as well as of m/e. In the case of cathode rays I did not

* Communicated by the Author: read at the Meeting of the British Association at Dover.

3079

3521

see my way to do this; but another case, where negative electricity is carried by charged particles (*i. e.* when a negatively electrified metal plate in a gas at low pressure is illuminated by ultra-violet light), seemed more hopeful, as in this case we can determine the value of e by the method I previously employed to determine the value of the charge carried by the ions produced by Röntgen-ray radiation (Phil. Mag. Dec. 1898). The following paper contains an account of measurements of m/e and e for the negative electrification discharged by ultra-violet light, and also of m/e for the negative electrification produced by an incandescent carbon filament in an atmosphere of hydrogen. I may be allowed to anticipate the description of these experiments by saying that they lead to the result that the value of m/e in the case of the ultra-violet light, and also in that of the carbon filament, is the same as for the cathode rays; and that in the case of the ultra-violet light, e is the same in magnitude as the charge carried by the hydrogen atom in the electrolysis of solutions. In this case, therefore, we have clear proof that the ions have a very much smaller mass than ordinary atoms; so that in the convection of negative electricity at low pressures we have something smaller even than the atom, something which involves the splitting up of the atom, inasmuch as we have taken from it a part, though only a small one, of its mass.

The method of determining the value of m/e for the ions carrying the negative electrification produced by ultra-violet light is as follows:—Elster and Geitel (Wied. *Ann.* xli. p. 166) have shown that the rate of escape of the negative electrification at low pressures is much diminished by magnetic force if the lines of magnetic force are at right angles to the lines of electric force. Let us consider what effect a magnetic force would have on the motion of a negatively electrified particle. Let the electric force be uniform and parallel to the axis of x, while the magnetic force is also uniform and parallel to the axis of z. Let the pressure be so low that the mean free path of the particles is long compared with the distance they move while under observation, so that we may leave out of account the effect of collisions on the movements of the particles.

If m is the mass of a particle, e its charge, X the electric force, H the magnetic force, the equations of motion are:—

$$m\frac{d^2x}{dt^2} = Xe - \mathrm{H}e\frac{dy}{dt},$$

$$m\frac{d^2y}{dt^2} = \mathrm{H}e\frac{dx}{dt}.$$

3080

3522

Eliminating x we have :—

$$m\frac{d^2y}{dt^2} = \frac{He}{m}\left(Xe - He\frac{dy}{dt}\right).$$

The solutions of these equations, if x, y, dx/dt, dy/dt all vanish when $t=0$, is expressed by

$$y = \frac{Xm}{eH^2}\left\{\frac{e}{m}Ht - \sin\left(\frac{e}{m}Ht\right)\right\},$$

$$x = \frac{Xm}{eH^2}\left\{1 - \cos\left(\frac{e}{m}Ht\right)\right\}.$$

The equations show that the path of the particle is a cycloid, the generating circle of which has a diameter equal to $2Xm/eH^2$, and rolls on the line $x=0$.

Suppose now that we have a metal plate AB exposed to ultra-violet light, placed parallel to a larger metal plate CD perforated so as to allow the light to pass through it and fall upon the plate AB. Then, if CD is at a higher electric potential than AB, all the negatively electrified particles which start from AB will reach CD if this plate is large compared with AB, the particles travelling along the lines of electric force. Let us now suppose that a uniform magnetic force equal to H, and at right angles to the electric force, acts on the particles; these particles will now describe cycloids and will reach a distance $2Xm/eH^2$ from the place from which they start, and after reaching this distance they will again approach the plate. Thus if the plate CD is distant from AB by less than $2Xm/eH^2$, every particle which leaves AB will reach CD provided CD stretches forward enough to prevent the particles passing by on one side. Now the distance parallel to y through which the particle has travelled when it is at the greatest distance from AB is $\pi Xm/eH^2$: hence if CD stretches beyond AB by this distance at least, all the particles will be caught by CD and the magnetic field will produce no diminution in the rate of leak between AB and CD. If, on the other hand, the distance between the plates is greater than $2Xm/eH^2$, then a particle starting from AB will turn back before it reaches CD: it will thus never reach it, and the rate at which CD acquires negative electrification will be diminished by the magnetic force. Hence, if this view of the action of the magnetic field is correct, if we begin with the plates very near together and gradually increase the distance between them, we should expect that, at first with the plates quite close together, the rate at which CD received a negative charge would not be affected by the magnetic force, but as

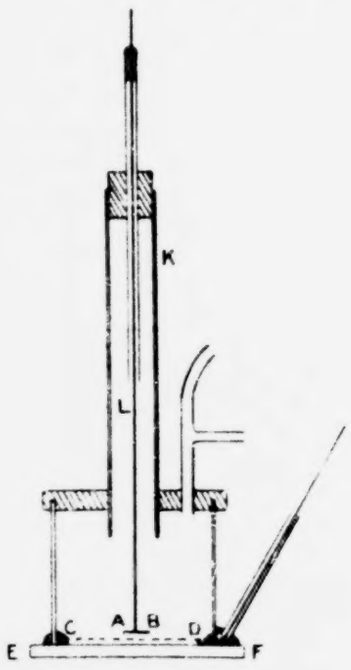
3081

3523

soon as the distance between the plates was equal to $2X\,meH^2$ the magnetic force would greatly diminish the rate at which CD received a negative charge, and would in fact reduce the rate almost to zero if all the negatively electrified particles came from the surface of AB. Hence, if we measure the distance between the plates when the magnetic force first diminishes the rate at which CD receives a negative charge, we shall determine the value of $2Xm/eH^2$; and as we can easily determine X and H, we can deduce the value of m/e.

The way in which this method was carried into practice was as follows, the apparatus being shown in fig. 1.

Fig. 1.



AB is a carefully polished zinc plate about 1 centim. in diameter, while CD is a grating composed of very fine wires crossing each other at right angles, the ends being soldered into a ring of metal; the wires formed a network with a mesh about 1 millim. square. This was placed parallel to AB on the quartz plate EF, which was about 1 millim. thick. The grating was very carefully insulated. The system was enclosed in a glass tube which was kept connected with a mercury-pump provided with a McLeod gauge. The ultra-violet light was supplied from an arc about 3 millim. long between zinc terminals. The induction-coil giving the arc was placed in a metal box, and the light passed through a window cut in the top of the box; over this window the quartz base of the vessel was placed, a piece of wire gauze connected with the earth being placed between the quartz and the window. The plate AB was carried by the handle L which passed through a sealing-wax stopper in the tube K. The magnet used was an electromagnet of the horseshoe type. The magnetic force due to the magnet was determined by observing the deflexion of a ballistic galvanometer when an exploring coil, of approximately the same vertical dimen-

3082

3524

sion as the distance between the plates AB and CD, was withdrawn from between its poles. The coil was carefully placed so as to occupy the same part of the magnetic field as that occupied by the space between AB and CD when the magnet was used to affect the rate of leak of electricity between AB and CD. In this way the intensity of the magnetic field between the poles of the magnet was determined for a series of values of the current through the magnetizing-coils of the electromagnet ranging between 1 and 15 amperes, and a curve was drawn which gave the magnetic force when the magnetizing-current (observed by an amperemeter) was known.

The pressure of the gas in the tube containing the plate was reduced by the mercury-pump to 1/100 of a millim. of mercury. As the mean free path of hydrogen molecules at atmospheric pressure and 0° C. is $1{\cdot}85 \times 10^{-5}$ centim. (Emil Meyer, *Kinetische Theorie der Gase*, p. 142), and of air 10^{-5} centim., the mean free paths of these gases at the pressure of 1/100 of a millim. of mercury are respectively 11 and 7·6 millim., and are consequently considerably greater than the greatest distance, 1 millim., through which the electrified particles have to travel in any of the experiments. These are the free paths for molecules of the gas; if, as we shall see reason to believe, the actual carriers of the negative electrification are much smaller than the molecules, the free paths of these carriers will be larger than the numbers we have quoted.

The rate of leak of negative electricity to CD when AB was exposed to ultra-violet light was measured by a quadrant-electrometer. The zinc plate was connected with the negative pole of a battery of small storage-cells, the positive pole of which was put to earth. One pair of the quadrants of the electrometer was kept permanently connected with the earth, the other pair of quadrants was connected with the wire gauze CD. Initially the two pairs of quadrants were connected together, the connexion was then broken, and the ultra-violet light allowed to fall on the zinc plate: the negative charge received by the wire gauze in a given time is proportional to the deflexion of the electrometer in that time. By this method the following results were obtained: when the difference of potential between the illuminated plate and the wire gauze was greater than a certain value depending upon the intensity of the magnetic force and the distance between AB and CD, no diminution in the deflexion of the electrometer was produced by the magnetic field, in fact in some cases the deflexion was just a little greater in the magnetic field. The theory just given indicates that the deflexion

3063

3525

ought to be the same: the small increase (amounting to not more than 3 or 4 per cent.) may be due to the obliquity of the path of the particles in the magnetic field, causing more of them to be caught by the wires of the grating than would be the case if the paths of the particles were at right angles to the plane of the gauze. When the difference of potential is reduced below a certain value, the deflexion of the electrometer is very much reduced by the magnetic field; it is not, however, at once entirely destroyed when the potential-difference passes through the critical value. The simple theory just given would indicate a very abrupt transition from the case when the magnetic force produces no effect, to that in which it entirely stops the flow of negative electricity to CD. In practice, however, I find that the transition is not abrupt: after passing a certain difference of potential the diminution in the electric charge received by CD increases gradually as the potential-difference is reduced, and there is not an abrupt transition from zero effect to a complete stoppage of the leak between AB and CD. I think this is due to the ionization not being confined to the gas in contact with the illuminated plate, but extending through a layer of gas whose thickness at very low pressures is quite appreciable. The existence of a layer of this kind is indicated by an experiment of Stoletow's. Stoletow found that the maximum current between two plates depended at low pressures to a considerable extent upon the distance between the plates, increasing as the distance between the plates was increased. Now the maximum current is the one that in one second uses up as many ions as are produced in that time by the ultra-violet light. If all the ions are produced close to the illuminated plate, increasing the distance between the plates will not increase the number of ions available for carrying the current; if, however, the ions are produced in a layer of sensible thickness, then, until the distance between the plates exceeds the thickness of this layer, an increase in the distance between the plates will increase the number of ions, and so increase the maximum current. If this layer has a sensible thickness, then the distance d which has to be traversed by the ions before reaching the gauze connected with the electrometer ranges from the distance between the plates to the difference between this distance and the thickness of the layer. The first ions to be stopped by the magnetic field will be those coming from the surface of the illuminated plate, as for these d has the greatest value: hence we may use the equation

$$d = \frac{2Xm}{eH^2} \quad \ldots\ldots\ldots \quad (1)$$

3084

3526

if d represents the distance between the plates, X the value of the electric field when the rate of leak first begins to be affected by the magnetic force H. Assuming that the field is uniform,

$$X = V/d,$$

where V is the potential-difference between the plates; and equation (1) becomes

$$d^2 = \frac{2Vm}{eH^2}$$

The negative ions travelling between the plates will disturb to some extent the uniformity of the field between the plates; but if the intensity of the ultra-violet light is not too great, so that the rate of leak and the number of ions between the plates is not large, this want of uniformity will not be important. A calculation of the amount of variation due to this cause showed that its effect was not large enough to make it worth while correcting the observations for this effect, as the variation in the intensity of the ultra-violet light was sufficient to make the errors of experiments much larger than the correction.

The following is a specimen of the observations:—

Distance between the plates ·29 centim.

Strength of magnetic field 164. Pressure 1/100 millim.

Potential-difference between Plates, in volts.	Deflexion of Electrometer in 30 secs.	
	Magnet off.	Magnet on.
240	180	190
120	180	165
80	180	140
60	180	75

These observations showed that the critical value of the potential-difference was about 80 volts. A series of observations were then made with potential-differences increasing from 80 volts by 2 volts at a time and it was found that 90 volts was the largest potential-difference at which any effect due to the magnet could be detected. The results of a number of experiments are given in the following table:—

3085

3527

d (in cm.)	H.	V in absolute measure.	e/m.
·18	170	40×10^8	$8\cdot5\times10^6$
·19	170	30×10^8	$5\cdot8\times10^6$
·20	181	38×10^8	$7\cdot0\times10^6$
·29	167	84×10^8	$7\cdot1\times10^6$
·29	164	90×10^8	$7\cdot6\times10^6$
·30	160	86×10^8	$7\cdot4\times10^6$
·45	100	80×10^8	$7\cdot9\times10^6$

giving a mean value for e/m equal to $7\cdot3\times10^6$. The value I found for e/m for the cathode rays was 5×10^6; the value found by Lenard was $6\cdot4\times10^6$. Thus the value of e/m in the case of the convection of electricity under the influence of ultra-violet light is of the same order as in the case of the cathode rays, and is very different from the value of e/m in the case of the hydrogen ions in ordinary electrolysis when it is equal to 10^4. As the measurements of e, the charge carried by the ions produced by ultra-violet light to be described below, show that it is the same as e for the hydrogen ion in electrolysis, it follows that the mass of the carrier in the case of the convection of negative electricity under the influence of ultra-violet light is only of the order of 1/1000 of that of the hydrogen atom. Thus with ultra-violet light, as with cathode rays, the negative electrification at low pressures is found associated with masses which are exceedingly small fractions of the smallest mass hitherto known—that of the hydrogen atom.

I have examined another case in which we have convection of electricity at low pressures by means of negatively electrified particles—that of the discharge of electricity produced by an incandescent carbon filament in an atmosphere of hydrogen. In this case, as Elster and Geitel (Wied. *Ann.* xxxviii. p. 27) have shown, we have negative ions produced in the neighbourhood of the filament, and the charge on a positively electrified body in the neighbourhood of the filament is discharged by these ions, while if the body is negatively electrified it is not discharged. If the filament is negatively, and a neighbouring body positively electrified, there will be a current of electricity between the filament and the body, while there will be no leak if the filament is positively and the body negatively electrified. Elster and Geitel (Wied.

3528

Ann. xxxviii. p. 27) showed that the rate of leak from a negatively electrified filament was at low pressures diminished by the action of the magnetic field. On the theory of charged ions, the effect of the magnet in diminishing the rate of leak could be explained in the same way as the effect on the convection due to ultra-violet light. A series of experiments were made which showed that the effects due to the magnetic field were consistent with this explanation, and led to a determination of e/m for the carriers of the negative electricity.

The apparatus was of the same type as that used in the preceding experiments. The wire gauze and the zinc plate were replaced by two parallel aluminium disks about 1·75 centim. in diameter; between these disks, and quite close to the upper disk, there was a small semicircular carbon filament which was raised to a red heat by the current from four storage-cells. The carbon filament was placed close to the axis of the disks; the object of the upper disk was to make the electric field between the disks more uniform. The lower plate was connected with the electrometer. The plates and filaments were enclosed in a glass tube which was connected with a mercury-pump, by means of which the pressure, after the vessel had been repeatedly filled with hydrogen, was reduced to ·01 millim. of mercury. Great difficulty was found at first in getting any consistent results with the incandescent carbon filament: sometimes the filament would discharge positive as well as negative electricity; indeed sometimes it would discharge positive and not negative. Most of these irregularities were traced to gas given out by the incandescent filament; and it was found that by keeping the filament almost white-hot for several hours, and continually pumping and refilling with hydrogen, and then using the filament at a much lower temperature than that to which it had been raised in this preliminary heating, the irregularities were nearly eliminated, and nothing but negative electrification was discharged from the filament. When this state was attained, the effect of magnetic force showed the same characteristics as in the case of ultra-violet light. When the difference of potential between the filament and the lower plate was small, the effect of the magnetic force was very great, so much so as almost to destroy the leak entirely; when, however, the potential-difference exceeded a certain value, the magnetic force produced little or no effect upon the leak. An example of this is shown by the results of the following experiment:—

3087

3529

The distance between the carbon filament and the plate connected with the electrometer was 3·5 millim., the strength of the magnetic field 170 C.G.S. units.

Difference of Potential between wire and plate, in volts.	Leak in 5 seconds.		Ratio of leaks
	Without magnetic field.	With magnetic field.	
40	43	1	·023
80	170	50	·29
120	300	250	·83
140	345	343	1·0
160	400	430	1·07

Taking 140 volts as the critical value of the potential-difference, we find by equation (1) that

$$\frac{e}{m} = 7{\cdot}8 \times 10^6.$$

The results of this and similar experiments are given in the following table; V denoting the critical potential-difference in C.G.S. units, and H the magnetic force:

d.	V.	H	e/m.
·35	140×10^8	170	$7{\cdot}8 \times 10^6$
·35	220×10^8	220	$7{\cdot}5 \times 10^6$
·35	170×10^8	170	$9{\cdot}6 \times 10^6$
·35	130×10^8	170	$7{\cdot}2 \times 10^6$
·35	120×10^8	120	$11{\cdot}3 \times 10^6$

giving $8{\cdot}7 \times 10^6$ as the mean value of e/m. This value does not differ much from that found in the case of ultra-violet light. In the case of the incandescent filament the ions are only produced at a small part of the plate, and not over the whole surface as in the case of ultra-violet light, so the conditions do not approximate so closely to those assumed in the theory. We conclude that the particles which carry the negative electrification in this case are of the same

PHOTOSTATED BY

35330

nature as those which carry it in the cathode rays and in the electrification arising from the action of ultra-violet light.

The unipolar positive leak which occurs from an incandescent platinum wire in air or oxygen, and in which the moving bodies are positively electrified, was found not to be affected by a magnetic field of the order of that used in the experiments on the negative leak. This had already been observed by Elster and Geitel (Wied. *Ann.* xxxviii. p. 27).

On the theory of the effect given in this paper, the absence of magnetic effect on the positively charged carriers indicates that e/m is much smaller or m/e much larger for the positive ions than it is for the negative. I am engaged with some experiments on the effect of the magnetic field on the convection of electricity by positive ions, using very strong magnetic fields produced by a powerful electromagnet kindly lent to me by Professor Ewing. From the results I have already got, it is clear that m/e for the positive ions produced by an incandescent wire must be at least 1000 times the value for the negative ions, and this is only an inferior limit.

The positive and negative ions produced by incandescent solids show the same disproportion of mass as is shown by the positive and negative ions in a vacuum-tube at low pressures. W. Wien (Wied. *Ann.* lxv. p. 440) and Ewers (Wied. *Ann.* lxix. p. 187) have measured the ratio of m/e for the positive ions in such a tube, and found that it is of the same order as the value of m/e in ordinary electrolysis; Ewers has shown that it depends on the metal of which the cathode is made. Thus the carriers of positive electricity at low pressures seem to be ordinary molecules, while the carriers of negative electricity are very much smaller.

Measurement of the Charge on the Ion produced by the Action of Ultra-Violet Light on a Zinc Plate.

This charge was determined by the method used by me to measure the charge on the ions produced by the action of Röntgen rays on a gas (Phil. Mag. Dec. 1898); for the details of the method I shall refer to my former paper, and here give only an outline of the principle on which the method is based. Mr. C. T. R. Wilson (Phil. Trans. 1898) discovered that the ions produced by ultra-violet light act like those produced by Röntgen rays, in forming nuclei around which water will condense from dust-free air when the supersaturation exceeds a certain definite value.

Suppose, then, we wish to find the number of ions produced by ultra-violet light in a cubic centimetre of air. We cool the air by a sudden expansion until the supersaturation

3089

3531

produced by the cooling is sufficient to form a cloud round the ions: the problem of finding the number of ions per cub. centim. is now reduced to finding the number of drops per cub. centim. in this cloud. We can do this in the following way:—If we know the amount of the expansion we can calculate the amount of water deposited per cub. centim. of the cloud; this water is deposited as drops, and if the drops are of equal size, the number of drops per cub. centim. will be equal to the volume of water per cub. centim. divided by the volume of one of the drops. Hence, if we know the size of the drops, we can calculate the number. The size of the drops in the cloud was determined by observing v, the velocity with which they fall under gravity, and then deducing a, the radius of the drop, by means of the equation

$$v = \frac{2}{9}\frac{ga^2}{\mu},$$

where μ is the coefficient of viscosity of the gas through which the drop falls.

In this way we can determine n the number of ions per cub. centim.: if e is the charge on an ion, v the velocity with which it moves under a known electric force, the quantity of electricity which crosses unit area in unit time under this force is equal to $ne nu$. We can determine this quantity if we allow the negative ions to fall on a plate connected with a condenser of known capacity and measure the rate at which the potential falls. We thus determine the product $ne nu$, and we already know u; u has been determined by Mr. Rutherford (Proc. Camb. Phil. Soc. ix. p. 401); for air at atmospheric pressure u is proportional to the potential gradient, and when this is one volt per centim., u is 1·5 centim. per second; for hydrogen at atmospheric pressure u is 4·5 centim. per second for the same potential gradient. Hence, as in the known product $ne nu$ we know u and u, we can deduce the value of e the charge on the ion.

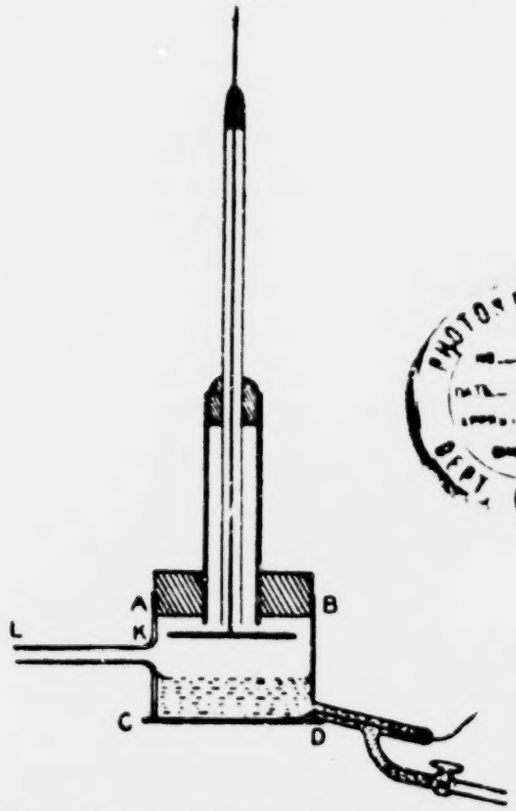
There are some features in the condensation of clouds by ultra-violet light which are not present in the clouds formed by the Röntgen rays. In the first place, the cloud due to the ultra-violet light is only formed in an electric field. When there is no electric field, the ions remain close to the surface of the illuminated plate, and are not diffused through the region in which the cloud has to be formed; to get the negative ions into this region we must electrify the plate negatively; when this is done, expansion produces a cloud. Again, if the ultra-violet light is very strong, Mr. C. T. R. Wilson has shown (Phil. Trans. 1899) that large nuclei are produced

3090

3532

in the gas through which the light passes; these are distinct from those produced near a metal plate on which the light falls, and they can produce a cloud with very little supersaturation; these nuclei are not ions, for they do not move in an electric field, and the drops formed round these nuclei ought therefore not to be counted in estimating the number of negative ions. For this reason it is necessary to use ultra-violet light

Fig. 2.



PHOTOSTATED BY DEPT. OF JUSTICE

of small intensity, and there are in addition other reasons which make it impossible to work with strong light. I found when working with the ions produced by Röntgen rays, that it was impossible to get good results unless the rays were weak and the clouds therefore thin. If the rays were strong, one expansion was not sufficient to bring down all the ions by the cloud; sometimes as many as five or six expansions were required to remove the ions from the vessel. Another

3091

35383

reason why the strong rays do not give good results is that there are slight convection-currents in the vessel after the expansion, for the walls of the vessel are warmer than the gas; this gives rise to convection-currents in the gas, the gas going up the sides and down the middle of the vessel. The velocity of the convection-current is added on to the velocity of the ions due to gravity; and if the velocity of the ions is very small, as it is when the rays are strong and the drops numerous, a very small convection-current will be sufficient to make the actual rate of fall of the drops very different from that of a drop of the same size falling through air at rest. All the reasons are operative in the case of ultra-violet light, and it is only when the intensity of the light is small that I have got consistent results.

The vessel in which the expansion took place is shown in fig. 2. AB is a glass tube about 3·6 cm. in diameter; the base CD is a quartz plate about ·5 cm. thick; on the top of this there is a layer of water in electrical connexion with the earth about 1 cm. in thickness; the illuminated zinc plate was 3·2 cm. in diameter, and was 1·2 cm. above the surface of the water. The ultra-violet light was produced by an arc about ·3 cm. long, between zinc terminals connected with an induction-coil; the arc was about 40 cm. below the lower face of the quartz plate. The space between the zinc plate and the water surface was illuminated by an arc-light so as to allow the rate of fall of the drops to be accurately measured. The tube LK connected this vessel with the apparatus used in the previous experiments; a figure of this is given in the Phil. Mag. Dec. 1898.

To observe the current of electricity through the gas, the illuminated plate was connected with one pair of quadrants of an electrometer, the other pair of quadrants being kept connected with the earth. The capacity C of the system, consisting of the plate, connecting wires and quadrants of the electrometer, was determined. The plate was then charged to a negative potential, and the deflexion of the electrometer-needles observed. The induction-coil was now set in action, and the ultra-violet light allowed to fall on the zinc plate; the deflexion of the electrometer-needle immediately began to decrease; the rate at which it decreased was determined by measuring the diminution of the deflexion in 30 seconds.

Let D be the original deflexion of the electrometer, let this correspond to a potential-difference equal to αD between the plate and the earth. If h is the distance between the zinc plate and the surface of the water, the potential gradient is $\alpha D/h$. If A is the area of the plate, n the number of ion-

3534

per cub. centim., e the charge on an ion, u_0 the velocity of the ion under unit potential gradient, then the quantity of negative electricity lost by the plate in one second is

$$A n e u_0 \alpha D / l.$$

But the plate is observed to fall in potential by $\alpha/$ per second, and the capacity of the system attached to the plate is C; hence the loss of electricity by the plate per second is

$$C \alpha l.$$

Equating these two expressions for the loss of electricity, we get

$$A n e u_0 \alpha D / l = C \alpha l$$

or

$$e = \frac{l^2 C d}{n u_0 A D}$$

Hence knowing l, C, A, and u_0, if we measure n and d D we can determine e.

To calculate n we begin by finding the volume of water deposited in consequence of the expansion in each cub. centim. of the expansion. In my previous paper I show how this can be determined if we know the ratio of the final to the initial volumes and the temperature before expansion. In the present experiments the final volume was 1·36 times the initial volume, and the temperature before expansion was 18°·5 C. It follows from this that 50×10^{-7} cub. centim. of water were deposited in each cub. centim. of the expansion chamber.

If a is the radius of one of the drops, the volume of a drop is $4\pi a^3/3$, and hence $n' = \frac{3 \times 50 \times 10^{-7}}{4\pi a^3}$; here n' is the number of ions per cub. centim. of the expanded gas.

If v is the velocity of fall

$$v = \frac{2}{9} \frac{g a^2}{\mu}$$

Since for air $\mu = 1{\cdot}8 \times 10^{-4}$, we find

$$a = \frac{v^{\frac{1}{2}}}{1{\cdot}1 \times 10^{3}}$$

and

$$\frac{4}{3}\pi a^3 = 3{\cdot}14\, v^{\frac{3}{2}} \times 10^{-9}$$

$$n' = \frac{5000}{3{\cdot}14\, v^{\frac{3}{2}}}$$

3093

3565

This is the number in 1 cub. centim. of the expanded gas; the number in 1 cub. centim. of the gas before expansion is $1{\cdot}36\,n'$. To find n the number of ions we must subtract from $1{\cdot}36\,n'$ the number of drops which are formed when the ultra-violet light does not fall on the plate. With an expansion as large as 1·36, Mr. Wilson has shown that a few drops are always formed in dust-free air, even when free from the influence of Röntgen rays or ultra-violet light. If V be the velocity with which these drops formed in the absence of the light fall, then the number of drops due to these nuclei is

$$\frac{1{\cdot}36\times 5000}{3{\cdot}14\,Vt}.$$

Subtracting this from $1{\cdot}36\,n'$, we find

$$n=2{\cdot}07\times 10^3\left\{\frac{1}{rt}-\frac{1}{Vt}\right\}.$$

In making this correction we have assumed that the clouds form round these nuclei even when the negative ions due to the ultra-violet light are present. If the cloud formed more readily about the negative ions than about the nuclei, the ions would rob the nuclei of their water, and we should not need the correction. The following table gives the result of some experiments; in making the observation on the cloud the same potential-difference between the plate and the water was used as when observing the value of d/D: u_0 was determined by Prof. Rutherford as $1{\cdot}5\times 3\times 10^2$, and A was $\pi(1{\cdot}6)^2$ throughout the experiments.

b.	C.	d/D.	r.	V.	$e\times 10^{10}$
1·2	62	·0017	·15	·3	7·9
1·2	62	·0019	·11	·3	7·3
·9	50	·0012	·14	·3	5·3
1·2	65	·0035	·08	·3	7·3

1·2	40	·0018	·14	·3	7

The mean value of e is $6{\cdot}8\times 10^{-10}$. The values differ a good deal, but we could not expect a very close agreement unless we could procure an absolutely constant source of ultra-violet light, as these experiments are very dependent on the constancy of the light; since the electrical part of the experiment measures the average intensity of the light over 30

PHOTOGRAPHED BY

3094

3536

seconds, while the observations on the cloud measure the intensity over an interval of a small fraction of a second.

The value of e found by me previously for the ions produced by Röntgen rays was $6{\cdot}5 \times 10^{-10}$: hence we conclude that e for the ions produced by ultra-violet light is the same as e for the ions produced by the Röntgen rays; and as Mr. Townsend has shown that the charge on these latter ions is the same as the charge on an atom of hydrogen in electrolysis, we arrive at the result previously referred to, that the charge on the ion produced by ultra-violet light is the same as that on the hydrogen ion in ordinary electrolysis.

The experiments just described, taken in conjunction with previous ones on the value of m/e for the cathode rays (J. J. Thomson, Phil. Mag. Oct. 1897), show that in gases at low pressures negative electrification, though it may be produced by very different means, is made up of units each having a charge of electricity of a definite size; the magnitude of this negative charge is about 6×10^{-10} electrostatic units, and is equal to the positive charge carried by the hydrogen atom in the electrolysis of solutions.

In gases at low pressures these units of negative electric charge are always associated with carriers of a definite mass. This mass is exceedingly small, being only about $1{\cdot}4 \times 10^{-3}$ of that of the hydrogen ion, the smallest mass hitherto recognized as capable of a separate existence. The production of negative electrification thus involves the splitting up of an atom, as from a collection of atoms something is detached whose mass is less than that of a single atom. We have not yet data for determining whether the mass of the negative atom is entirely due to its charge. If the charge is e, the apparent mass due to the charge supposed to be collected on a sphere of radius a is $\frac{1}{3}e^2/\mu a$: hence m/e in this case is $e/3\mu a$. Substituting the values of m/e and e found above, we find that a would be of the order 10^{-13} centim.

We have no means yet of knowing whether or not the mass of the negative ion is of electrical origin. We could probably get light on this point by comparing the heat produced by the bombardment by these negatively electrified particles of the inside of a vessel composed of a substance transparent to Röntgen rays, with the heat produced when the vessel was opaque to those rays. If the mass was "mechanical," and not electrical, the heat produced should be same in the two cases. If, on the other hand, the mass were electrical, the heat would be less in the first case than in the second, as part of the energy would escape through the walls.

3095

3537

Hitherto we have been considering only negative electrification; as far as our present knowledge extends positive electrification is never associated with masses as small as those which invariably accompany negative electrification in gases at low pressures. From W. Wien's experiments on the ratio of the mass to the electric charge for the carriers of positive electrification in a highly exhausted vacuum-tube (Wied. *Ann.* lxv p. 440), it would seem that the masses with which positive electrification is associated are comparable with the masses of ordinary atoms. This is also in accordance with the experiments of Elster and Geitel (Wied. *Ann.* xxxviii. p. 27), which show that when positive ions are produced by an incandescent platinum wire in air they are not affected to anything like the same extent as negative ions produced by an incandescent carbon filament in hydrogen.

It is necessary to point out that the preceding statements as to the masses of the ions are only true when the pressure of the gas is very small, so small that we are able to determine the mass of the carriers before they have made many collisions with the surrounding molecules. When the pressure is too high for this to be the case, the electric charge, whether positive or negative, seems to act as a nucleus around which several molecules collect, just as dust collects round an electrified body, so that we get an aggregate formed whose mass is larger than that of a molecule of a gas.

The experiments on the velocities of the ions produced by Röntgen or uranium rays, by ultra-violet light, in flames or in the arc, show that in gases at pressures comparable with the atmospheric pressure, the electric charges are associated with masses which are probably several times the mass of a molecule of the gas, and enormously greater than the mass of a carrier of negative electrification in a gas at a low pressure.

There are some other phenomena which seem to have a very direct bearing on the nature of the process of ionizing a gas. Thus I have shown (Phil. Mag. Dec. 1898) that when a gas is ionized by Röntgen rays, the charges on the ions are the same whatever the nature of the gas: thus we get the same charges on the ions whether we ionize hydrogen or oxygen. This result has been confirmed by J. S. Townsend ("On the Diffusion of Ions," Phil. Trans. 1899), who used an entirely different method. Again, the ionization of a gas by Röntgen rays is in general an additive property; *i. e.*, the ionization of a compound gas AB, where A and B represent the atoms of two elementary gases, is one half the sum of the ionization of A_2 and B_2 by rays of the same intensity, where

3096

3538

A_2 and B_2 represent diatomic molecules of these gases (Proc. Camb. Phil. Soc. vol. x. p. 9). This result makes it probable that the ionization of a gas in these cases results from the splitting up of the atoms of the gas, rather than from a separation of one atom from the other in a molecule of the gas.

These results, taken in conjunction with the measurements of the mass of the negative ion, suggest that the ionization of a gas consists in the detachment from the atom of a negative ion; this negative ion being the same for all gases, while the mass of the ion is only a small fraction of the mass of an atom of hydrogen.

From what we have seen, this negative ion must be a quantity of fundamental importance in any theory of electrical action; indeed, it seems not improbable that it is the fundamental quantity in terms of which all electrical processes can be expressed. For, as we have seen, its mass and its charge are invariable, independent both of the processes by which the electrification is produced and of the gas from which the ions are set free. It thus possesses the characteristics of being a fundamental conception in electricity; and it seems desirable to adopt some view of electrical action which brings this conception into prominence. These considerations have led me to take as a working hypothesis the following method of regarding the electrification of a gas, or indeed of matter in any state.

I regard the atom as containing a large number of smaller bodies which I will call corpuscles; these corpuscles are equal to each other; the mass of a corpuscle is the mass of the negative ion in a gas at low pressure, i. e. about 3×10^{-26} of a gramme. In the normal atom, this assemblage of corpuscles forms a system which is electrically neutral. Though the individual corpuscles behave like negative ions, yet when they are assembled in a neutral atom the negative effect is balanced by something which causes the space through which the corpuscles are spread to act as if it had a charge of positive electricity equal in amount to the sum of the negative charges on the corpuscles. Electrification of a gas I regard as due to the splitting up of some of the atoms of the gas, resulting in the detachment of a corpuscle from some of the atoms. The detached corpuscles behave like negative ions, each carrying a constant negative charge, which we shall call for brevity the unit charge; while the part of the atom left behind behaves like a positive ion with the unit positive charge and a mass large compared with that of the negative ion. On this view, electrification essentially involves the splitting up of the atom, a part of the mass of the atom getting free and becoming detached from the original atom.

3097

35339

A positively electrified atom is an atom which has lost some of its "free mass," and this free mass is to be found along with the corresponding negative charge. Changes in the electrical charge on an atom are due to corpuscles moving from the atom when the positive charge is increased, or to corpuscles moving up to it when the negative charge is increased. Thus when anions and cations are liberated against the electrodes in the electrolysis of solutions, the ion with the positive charge is neutralized by a corpuscle moving from the electrode to the ion, while the ion with the negative charge is neutralized by a corpuscle passing from the ion to the electrode. The corpuscles are the vehicles by which electricity is carried from one atom to another.

We are thus led to the conclusion that the mass of an atom is not invariable: that, for example, if in the molecule of HCl the hydrogen atom has the positive and the chlorine atom the negative charge, then the mass of the hydrogen atom is less than half the mass of the hydrogen molecule H_2; while, on the other hand, the mass of the chlorine atom in the molecule of HCl is greater than half the mass of the chlorine molecule Cl_2.

The amount by which the mass of an atom may vary is proportional to the charge of electricity it can receive; and as we have no evidence that an atom can receive a greater charge than that of its ion in the electrolysis of solutions, and as this charge is equal to the valency of the ion multiplied by the charge on the hydrogen atom, we conclude that the variability of the mass of an atom which can be produced by known processes is proportional to the valency of the atom, and our determination of the mass of the corpuscle shows that this variability is only a small fraction of the mass of the original atom.

In the case of the ionization of a gas by Röntgen or uranium rays, the evidence seems to be in favour of the view that not more than one corpuscle can be detached from any one atom. For if more than one were detached, the remaining part of the atom would have a positive charge greater than the negative charge carried by each of the detached corpuscles. Now the ions, in virtue of their charges, act as nuclei around which drops of water condense when moist dust-free gas is suddenly expanded. If the positive charge were greater than the individual negative ones, the positive ions would be more efficient in producing cloudy condensation than the negative ones, and would give a cloud with smaller expansion. As a matter of fact, however, the reverse is the case, as C. T. R. Wilson (Phil. Trans. 1899) has shown that it requires a considerably greater expansion to produce a

Brevet de quinze ans demandé le 21 janvier 1903 par **M. Robert GILLET de VALBREUZE** (France).

Perfectionnements au mode de transmission par ondes électriques connu sous le nom générique de télégraphie sans fil.

Délivré le 7 mai 1903; publié le 18 juillet 1903.

Cette invention se rapporte à des perfectionnements au mode de transmission par ondes électriques connu sous le nom générique de télégraphie sans fil.

Il est nécessaire, pour bien comprendre le but de cette invention, de rappeler le principe des appareils actuels et les raisons pour lesquelles leur emploi ne permet pas d'obtenir la syntonisation. On emploie actuellement comme transmetteurs des excitateurs montés en dérivation sur le secondaire d'une bobine d'induction dont les extrémités sont reliées d'une part à la terre et d'autre part à l'antenne, soit directement soit par l'intermédiaire d'un transformateur. Pour les récepteurs on utilise les propriétés de certains contacts imparfaits dont la résistance électrique s'abaisse considérablement lors du passage d'une onde électromagnétique.

La sécurité des communications exige que les signaux émis par un transmetteur donné ne soient décelés que par un récepteur déterminé et que les signaux décelés par ce récepteur ne proviennent que du transmetteur donné. Pour obtenir cette syntonisation, il est absolument nécessaire d'accorder les mouvements vibratoires transmis avec les oscillations que le circuit récepteur serait capable d'émettre s'il était employé comme transmetteur; quand ces conditions sont remplies, c'est-à-dire quand la fréquence propre du récepteur est accordée avec la fréquence du transmetteur, il y a résonance entre les deux appareils, exactement comme entre deux diapasons accordés.

Les divers procédés de syntonisation imaginés jusqu'ici n'ont donné aucun résultat véritablement sélectif : la raison doit en être cherchée dans ce que l'on emploie comme transmetteur un excitateur. En effet, dans l'excitateur, l'étincelle remplit le rôle d'un déclenchement brutal entre deux charges contraires d'électricité et donne lieu dans le circuit transmetteur à des oscillations amorties dont l'amplitude et la période décroissent rapidement; en outre, les variations continuelles de la résistance, dues aux variations de l'étincelle oscillante, changent à chaque instant la nature des oscillations; la perturbation d'un excitateur est donc complexe et résulte de la superposition de nombreuses vibrations dissemblables. Or pour obtenir la syntonisation, il faut avoir recours aux phénomènes dits de résonance, et pour pouvoir faire de la résonance il faut qu'un régime permanent ait pu s'établir.

Le problème est donc insoluble avec les appareils actuels. Le système objet de cette invention permet d'obtenir la syntonisation avec des appareils reposant sur l'emploi de tubes à vide.

Prix du fascicule : 1 franc.

3101

RÉSUMÉ.

Les points caractéristiques de cette invention sont :

Dans les systèmes de transmission à distance par ondes électriques, connus sous le nom générique de télégraphie sans fil :

1° L'emploi d'un tube à vide accompagné d'un condensateur pour produire, avec l'énergie fournie par une source d'électricité, des courants alternatifs de fréquence très rapide et bien déterminée;

2° Emploi d'un organe dit soupape électrique, constitué par un tube à vide, ou de plusieurs soupapes semblables combinées entre elles, pour transformer en courants toujours de même sens les courants alternatifs de fréquence très rapide transmis aux appareils récepteurs.

Patent for fifteen years, filed January 21, 1903, by Mr. Robert Gillet de Balbreuze (France).

Improvements in the method of transmission by electric waves known under the generic name of telegraphy without wires.

Delivered May 7, 1903; published July 18, 1903.

This invention relates to improvements in the method of transmission by electric waves known under the generic name of wireless telegraphy.

It is necessary in order to well understand the object of this invention to recall the principle of the present apparatus-es and the reasons why their use does not permit of obtaining syntonism. There are at present employed as transmitters, exciters mounted in shunt on the secondary

of an induction coil, the extremities of which are connected on the one hand to the earth and on the other hand to the antenna, either directly or by means of a transformer. For the receivers there are utilized the properties of certain imperfect contacts, the electrical resistance of which is considerably lowered on the passage of an electromatic wave.

Safety of communication demands that the signals emitted by a given transformer be disclosed only by a pre-determined receiver, and that the signal disclosed by this receiver should come only from the respective transmitter. In order to obtain this syntonism, it is absolutely necessary to tune the vibratory movements transmitted with the oscillations which the receiving circuit would be capable of emitting, if it should be employed as a transmitter; when these conditions are fulfilled, that is to say, when the natural frequency of the receiver is tuned to the frequency of the transmitter, there is *resonance* between the two apparatuses, exactly as between two tuned tuning forks.

The various processes of syntonization devised up to the present time have given no truly selective result; the reason therefore is to be sought in the fact that an exciter is employed as a transmitter. In fact, in the exciter the spark fulfills the role of a rough release between two opposite charges of electricity, and gives rise in the transmitting circuit to damped oscillations, the amplitude and period of which decrease rapidly; moreover, the continual variations of the resistance, due to the variations of the oscillating spark, change the nature of the oscillation at every instant. [fol. 3108] The disturbance of an exciter is then complex, and follows from the superposition of numerous dissimilar vibrations. Now, in order to obtain syntonization, it is necessary to have recourse to phenomena called resonance, and to be able to produce resonance, it is necessary that a permanent regime may be able to be established.

The problem is then unsolvable with the present apparatus. The system forming the subject matter of this invention allows of obtaining syntonism with apparatus based upon the use of vacuum tubes.

In 1875 Mr. W. de LaRue, having subjected a vacuum tube to the action of a battery of 1080 elements, proved that the continuous, luminous vein was stratified as soon as there was interposed a condenser in parallel, and he shows that the circuit was then traversed by an alternating current of a very high frequency and very definite.

Recently Mr. Hewitt has brought to incandescence by the effect of a continuous current of 110 volts, a vacuum tube with mercury electrodes (Cooper Hewitt lamp). This tube requires a preliminary excitation obtained by means of a Ruhmkorff coil, or a coil of self-inductance.

Mounting a condenser in parallel with a Hewitt tube fed by a continuous current, there is obtained in the circuit an alternating current of very high and well determined frequency, as in the experiment of W. de LaRue. It is probable that by the aid of this same apparatus, suitably modified, we could succeed also in transforming industrial alternating current of low frequency into a current of high frequency.

The system forming the subject matter of this invention consists essentially in using as a transmitter, in transmissions to a distance, known commonly under the name of wireless telegraphy, a vacuum tube of the class mentioned above, accompanied by a condenser for the purpose of obtaining alternating currents of high frequencies suitable for the transmissions.

Fig. 1 of the annexed drawing represents diagrammatically an installation, according to this system, of transmitter for Morse signals.

A circuit comprises any source whatever A of continuous current of above 100 volts, and of a choking coil B, the vacuum tube C on primary D of a transformer without iron core. A condenser E and secondary f of a small Ruhmkorff coil F, serving for the excitation are mounted in parallel with this circuit. f^1 indicates the battery feeding this coil and f^2 the switch by which it is momentarily placed in circuit.

The transformer comprises two secondary coils D^1 and D^2, the extremities of one of them, D^1, are connected to earth, G, and to the transmitting antenna H, the extremities of the other, D^2, are connected to a damping circuit, I, comprising a not very large self-induction and a Morse key, J, serving for the transmission. The object of this arrangement is to not cool off the tube in the intervals of the dashes or dots representing the alphabet, as would [fols. 3109-3110] happen if the interruptor were cranched on the principal circuit. With this transmitter the antenna is the seat of induced currents of a constant amplitude, and of a high and well-determined frequency. Their period $t = 2\pi\sqrt{LC}$ should be rendered equal to the natural period of the

receiver $t^2 = 2. L'C'$ in order to have perfect resonance: for that LC' will be made equal to $L'C'$ by varying L by means of an additional self-induction coil, of a variable number of windings.

As receiver there is employed an apparatus which allows of re-transforming the alternating current into a continuous current, actuating a relay. For that recourse is had to apparatus called electric valves, placed as described hereinafter, and diagrammatically represented by Fig. 2. Two tubes K^1 and K^2 are taken, having for electrodes a point and ball very close together. The degree of vacuum is determined by the blue tint of the luminosity due to the passage of a current. It is probable that with tubes containing an electrode of mercury and an electrode of iron or of nickel, we should obtain similar valves applicable to strong currents). These tubes are mounted in multiple, the electrodes being opposite each other, and interposed in a circuit containing the secondary L of a transformer without iron core and a condenser M; the primary 1 of the transformer is in series with the antenna and the earth. Each of these two coils N^1 and N^2 of a polarized relay extremely sensitive, is mounted in series with one of the tubes. When an alternating current of high frequency is received by the antenna, it induces in the circuit a periodic current, the positive portions of which pass through one of the tubes, while the negative portions pass through *through* the other. The circuit A, K^1, N^1, B, N^2, K^2, A is then traversed by currents always of the same direction actuating the relay N^1, N^2; the self-induction of these two coils controls the redressed currents, and there is produced a current practically continuous.

Resume.

The characteristic points of this invention are:

In systems of transmitting to a distance by means of electric waves known under the generic name of wireless telegraphy.

1. The use of a vacuum tube accompanied by a condenser in order to produce, with the energy furnished by a source of electricity, alternating current of a very rapid and well determined frequency.

2. The use of a device called an electric valve formed by a vacuum tube, or of several similar valves combined together in order to transform into currents always in the

same direction, the alternating currents of very rapid frequency transmitted to the receiving apparatus.

By power of attorney, by Robert Gillet de Valbreuze.

The Thermionic Valve and its Developments in Radio Telegraphy and Telephony, by J. A. Fleming, 1919

Chapter III.—The Three-Electrode Valve

1. An improvement on the hot and single cold electrode oscillation valve described in the previous chapter was effected by the introduction of a second cold electrode in the form of a grid, wire zig-zag or perforated plate placed in between the hot cathode and cold electrode of the Fleming valve.

This modification enabled the appliance to be used not merely to rectify electric oscillations, but to relay or repeat them on a magnified scale, so that when employed with a telephone, as below described, a considerable increase in oscillation-detecting power ensued. Also it made it possible to use the instrument as a telegraphic relay of a certain kind. The credit for this structural improvement must be given to Dr. Lee de Forest, who arrived at it by a series of steps presently to be mentioned.

Underrating, however, the author's previous work in the invention of the two-electrode valve, he took the view that his improvement constituted a new invention originating entirely with himself, independent of everything that had been done before, and radically different in operation from the Fleming valve.

Hence he availed himself of many opportunities for disparaging the author's prior work, incorrectly, representing the two-electrode oscillation valve as a comparatively useless laboratory device appropriated from Mr. Edison, or else "taken from the early German scientists by Professor Fleming."[1]

---

[1] See letter of L. de Forest in *The Electrician*, vol. lxi., p. 804, September 4th, 1908. A prolonged controversy took place on this subject. See de Forest's letters in *The Electrician*, vol. lviii., p. 425, December 28th, 1906; vol. lxi.,

The judgment of Judge Mayer and the confirmatory unanimous judgment of the Court of Appeals in the action-at-law already mentioned in Chapter II have cleared away these misconceptions and shown that his improvements are of the nature of modifications of the original invention of the oscillation valve, but involve the same physical prin-[fol. 3112] ciples, and cannot be exercised in the United States of America in commercial manufacture without infringing certain claims in the author's fundamental valve patent as long as it remains in force.

The stages by which de Forest reached this modification or improvement, were as follows:- In or before 1904 he was engaged in researches on the production of some new detector devices he called "oscillation responsive devices," in which two electrodes were immersed in the flame of a Bunsen burner and connected respectively to the earth and to a receiving aerial. They were also joined by a circuit containing a battery and a telephone. The idea seems to have been that the oscillations in the aerial would put the "gaseous medium"—*i.e.*, the flame, "into a condition of molecular activity," and that it would then become a conductor and pass the current from the battery through the telephone in series with it and thus produce a sound.

He applied, on February 2nd, 1905, for a United States patent for these devices, the specification having been actually signed by him on November 4th, 1904, a few days before the application of the author for the British valve patent, No. 24,850, of 1904, and some weeks before the application for the corresponding United States patent, No. 803,684.

In this specification, No. 979,275, of 1905, Lee de Forest included amongst his Bunsen burner oscillation responsive devices one consisting of a bulb filled with air or gas, in which were two electrodes intended to be heated by a dynamo, but as the electrodes are shown in the diagram connected by a telephone, it is not at all clear how they could carry a heating current from the dynamo (see p. 106, Fig. 56*a*).

---

p. 804, September 4th, 1908; vol. lxi., p. 1006, October 9th, 1908; and vol. lxxii., p. 659, January 23rd, 1914. Also the author's replies in *The Electrician*, vol. lviii, p. 263, November 30th, 1906; vol. lviii., p. 464, January 4th, 1907; vol. lxi., p. 843, September 11th, 1908; vol. lxxii., p. 377, December 5th, 1913; vol. lxxii., p. 660, January 23rd, 1914.

The specification contains forty-one claims and abounds in such vague phrases as "a sensitive constantly receptive oscillation responsive device comprising in its construction a sensitive conducting gaseous medium." The various items in this United States patent of de Forest, No. 979,275, were subsequently divided into separate applications and formed the subject-matter of three subsidiary specifications—viz., No. 867,876, application of April 4th, 1906; No. 867,877, application of June 12th, 1907; No. 867,878, application of June 12th, 1907.

It is not at all certain that any of these devices were ever put into practical operation, but, nevertheless, their patentee referred to this United States patent, No. 979,275, some ten years afterwards as his "basic American patent."[2]

When, however, in 1916, the question of its real value came to be discussed impartially in a Court of Law, Judge Mayer, who tried the case, in giving judgment on September 20th, 1916, in the action brought by the Marconi Wireless Telegraph Company of America against de Forest Radio Telephone and Telegraph Company, after a prolonged legal contest on the Fleming and de Forest patents, said: "This burner detector of de Forest has never been commercially used and thus has not made any impression on the art. A mere inspection of the device in operation will show that [fol. 3113] this flickering flame is impracticable. The most that can be said for it is that it may contain the germ of an idea which in this rapidly progressing art may hereafter be utilised in some way. Whilst, therefore, it is not necessary to declare this patent and its three subsidiaries invalid, it may be eliminated from this case for all practical purposes."

Soon after the date of application for the Bunsen burner patent de Forest had brought to his notice the paper published by the author in the *Proceedings of the Royal Society of London* issue of March 16th, 1905, which had been read to the Society on February 9th of that year entitled, "On the Conversion of Electric Oscillations into Continuous Currents by means of a Vacuum Valve."

It is clear from subsequent events that this paper was the means of starting trains of though in his mind which had certainly not been there before its perusal. He must then

[2] See a letter by Dr. Lee de Forest to *The Electrician* (London), on January 23rd, 1914, vol. lxxii., p. 659; and reply by J. A. Fleming, *ibid.*, p. 660.

have become strongly impressed with the idea that what was required was not "a gaseous medium in a state of molecular activity," but some means of rectifying, as the author had shown, the trains of electric oscillations into unidirectional currents to make them affect a telephone or other instrument. Accordingly, in his next U. S. patent application, No. 823,402, filed December 9th, 1905, covering inventions in radiotelegraphy, we find he made use of the Fleming valve, and gave also a reference to its published description in the *Proceedings of the Royal Society*, March 16th, 1905.

Very ingeniously, however, he couples with this valve, and as equivalent to it, one of his Bunsen burner detectors, the flame of which is rendered more conducting by sodium or other salts, and this flame is now described as having a non-symmetrical conductivity. He states that positive electricity passes more readily in one direction in the flame than in the opposite.

The Bunsen burner had thus been transmitted into a rectifier of oscillations, and is described as a "valve" in this de Forest specification. His next step was to apply, on January 18th, 1906, for a United States patent, No. 824,637, for an oscillation-responsive device "of great simplicity and sensitiveness." In this specification great cleverness is shown in the treatment by which the oscillation responsive device, shown in his Bunsen burner patent, No. 979,275 (Fig. 6) and its subsidiary or divided application, No. 867,876, of April 4th, 1906, is gradually transformed into an identity with the author's oscillation valve, but disguised by the use of pseudo-scientific language, so as to appear to be something quite novel.

The glass bulb is described as a "receptacle," and the more or less perfect vacuum is a "gaseous medium, which is to be put into a condition of "molecular activity," "highly sensitive to electrical oscillations," when an electric current is employed "to heat two highly-resistant electrodes."

Diagrams are then given in this specification in which there is, as it were, a slow evolutionary transformation from the sterile oscillation responsive device of specification No. 979,275 (Fig. 6) to a nearly complete identity with the [fol. 3114] author's previously described valve detector. The diagrams *a*, *b*, *c*, *d*, in Fig. 56 are taken from de Forest's U. S. specifications, and show how ingeniously this metamorphosis was managed. The series, in fact, reminds us forcibly of the illustrations in books on geology, showing the gradual

evolution of present-day forms of animal life from ancient prehistoric types now extinct.

In the above specification it was stated that heating the electrodes is not even necessary, and that the gas may be "rendered sensitive to electrical oscillations by heating or by any other suitable means." As an example of such "suitable means" it is sufficient to cover the electrodes with "some radio-active substance such as radium bromid."

The next step was to sub-divide this broad specification into others covering its separate parts—viz., No. 836,070 (application of May 19th, 1906), and No. 836,071 (application of May 19th 1906). The first of these includes and describes identically the same article as a Fleming valve. The "receptacle" is now "partially exhausted." Two electrodes are sealed into it. One electrode, *E*, may be an "ordinary incandescent lamp carbon filament," the other "a disk of platinum or other material." The "gaseous medium" between them is rendered sensitive to electrical oscillations by the radiation of heat from the electrode, *E*, the said electrode being heated by a source of energy.

Influenced by this verbal camouflage, the United States Patent Office examiners could hardly help believing that the above specification described something entirely new and different from the simple Fleming valve for which a United States patent had been applied and issued months before, the only difference being that in the former specification the valve is shown associated with a telephone and

boosting battery as signal detector, and in the latter with a galvanometer or other current-detecting instrument.

In order to maintain the tradition that the Bunsen burner detector was the real parent of all subsequent forms of valve, Dr. Lee de Forest continued his course on January 20th, 1906, by filing an application, No. 824,638, for another Bunsen burner patent. In this case electrodes are placed in a Bunsen flame. "These may consist of platinum or carbon, or may be of platinum and the other of carbon." "When [fol. 3115] electrical oscillations are developed in the antenna by electromagnetic signal waves the passage of such oscillations through the sensitive gaseous conducting medium between the electrodes alters the conductivity thereof and thereby alters what may be termed the internal resistance of the flame battery constituted by the electrodes and the flame." There is no proof that any "sensitive gaseous medium" ever acted in this manner or that a single wireless message was ever received by this suggested form of "oscillation-responsive device."

In his next patent application the pendulum swings back again in the direction of the Fleming valve, and on February 14th, 1906, we find de Forest making another patent application, No. 837,901, in which he again declares he has "discovered that if a gaseous medium intervening between two separated electrodes be put into a condition of molecular activity by heating the same or otherwise putting it into a condition of molecular activity, said medium becomes highly sensitive to electrical oscillations." The actual instrument figured in the diagrams of this specification is, however, an incandescent electric lamp arranged as an oscillation valve having a projection on the bulb filled with mercury which acts as the cold electrode. An electromagnet is shown in the diagram placed near the bulb, which is said "will greatly increase the sensitiveness of the detector."

This application was followed by another on August 27th, 1906, No. 331,286, in which an oscillation detector is described which is said to have many uses. It comprises now "an exhausted vessel of glass or other suitable material, having two separated electrodes, between which intervenes the gaseous medium which when sufficiently heated or otherwise made highly conducting forms the sensitive element of the oscillation detector." One of these electrodes is to be a carbon or tantalum filament and the other a cold metal

plate or pair of plates. In the diagrams the filament is shown connected to a battery through a rheostat and outside the lamp the plates are connected with the lamp filament terminals through a telephone and a boosting battery. In some cases magnets are to be placed outside the bulb or coils of wire surrounding it.

In order carefully to distinguish this oscillation-responsive device from the Fleming valve, to which it had unfortunately so strong a resemblance, a new name for it was coined. It was called an *audion*. The patentee says this name is to include other devices of his invention "employing a conducting gaseous medium as the sensitive element."

It is curious how de Forest returns again and again in his specification to such meaningless expressions as the above.

2. Having secured, as he no doubt thought, a sound position — regard to patent priority, Dr. Lee de Forest next read a paper to the *in* American Institute of Electrical Engineers, New York, in October, 1906 (see *Transactions, American Institute of Electrical Engineers*, vol. xxv., p. 735, 1906), entitled "The Audion: A New Receiver for Wireless Telegraphy." The paper was discursive and also remarkable for the absense of any correct and proper history of the subject.

[fol. 3116] The author of it began by giving an account of his Bunsen burner experiments as the foundation of all his work and he then gives a single reference to a paper by Elster and Geitel, published in *Wiedemann's Annalen*, vol. xvi., 1882, and he also gives a diagram taken from one of their subsequent papers. The paper of Elster and Geitel which he quotes—viz., *Wied. Ann.*, vol. xvi., 1882—contains no reference to the diagram he gives of the apparatus, consisting of a glass bulb having a wire stretched across it, intended to be heated by an electric current, and an insulated metal plate placed near it and carried on a wire sealed through the glass (see Fig. 19 of Chap. I. of this book). The title of Elster and Geitel's 1882 paper is "On the Electricity of Flames," and no apparatus is described in this paper such as that de Forest depicts. This bulb was not used by Elster and Geitel until five years later and is described by them in a paper entitled "On the Ionisation of Gases by Incandescent Bodies," printed in *Wiedemann's Annalen* for 1887, vol. xxxi., p. 109.

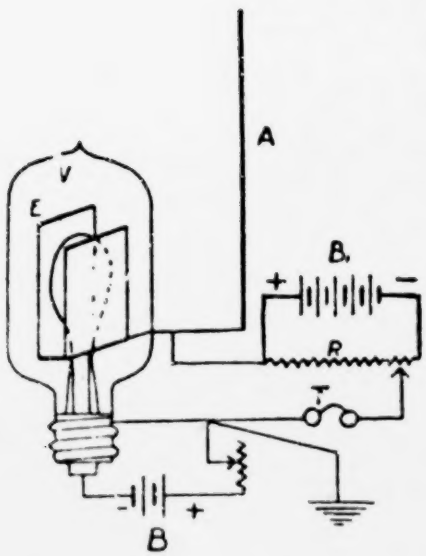

FIG. 57. Lee de Forest's Two-Electrode Audion of 1906

Moreover in this 1887 paper, Elster and Geitel only used a *platinum* wire across the bulb, and it was not until two years later, in 1889 (see *Wied. Annalen*, vol. xxxvii., p. 319, 1889), that they experimented with a carbon filament and found that it gave off negative electricity when incandescent.

It was in December, 1889, that the author sent to the Royal Society of London a paper dealing with the "Edison effect" in carbon glow lamps and in the electric arc and the transference of negative electricity from hot to cold electrodes in vacuum bulbs. There is not the slightest reference to this work in de Forest's paper.

This point is important, as it shows clearly the want of care and fairness in collecting information and verifying references. Moreover, de Forest refers to the author's prior work in connection with the use of a glow lamp having a plate sealed into the bulb for rectifying high frequency currents as experiments with an "Elster and Geitel tube" (see below). He then went on to describe as a new invention of his own a detector for wireless telegraphy consisting of a glass bulb evacuated of its air having in it a horseshoe-shaped filament of carbon or tantalum carried on wires sealed through the glass and rendered incandescent by the current from a battery. On either side of the filament were fixed two metal plates he calls "wings" carried on a platinum wire sealed through the glass. Outside the lamp the two plates were connected with the positive terminal of the filament through a circuit containing a [fol. 3117] galvanometer, a telephone, and a battery of cells having its positive terminal joined to the wings (see Fig. 57).

He omitted to mention that this arrangement had already been patented by the author in Great Britain as a radio-telegraphic detector. He also gave other diagrams of

audions with coils of wire round the lamp bulb, the diagrams being taken from his then recently filed United States Specification, No. 841,386.[3] Judging by the discussion which followed, his explanations of the action of his "audion" were not considered very satisfactory and objections were raised to his newly coined name as a bastard and unsuggestive word.

Broadly speaking, he attributed the operation to the ionisation of the residual gas by the incandescent filament, but he gave no very clear account of the physical processes at work. As regards the line of thought which led him to invent this detector, he stated that it occurred to him that the attenuated and ionised gases around an incandescent filament would undergo very considerable changes when subjected to Hertzian oscillations. He appeared chiefly desirous of proving that his audion was not an oscillation valve but something very superior to it. He strongly insisted that the important novel element was the use of a voltaic battery in series with the telephone supplying a boosting voltage and that this circuit was connected outside the lamp between the "wing" plates and the *positive* terminal of the incandescent filament.

He felt bound, however, to forestall some mention of the Fleming valve patented in Great Britain nearly two years before, and fully described in the author's book, *Principles of Electric Wave Telegraphy*, published nearly six months before the date when he read his paper. Hence he says, *loc. cit.*: "I have arrived as yet at no completely satisfactory theory as to the exact means by which the high frequency oscillations affect so markedly the behaviour of an ionised gas. Fleming points out that when the cold plate of an Elster-Geitel tube is connected to the positive end of the filament and the two put in a high-frequency oscillation circuit, only the positive half of the oscillation can pass from the plate to the filament across the gas. He uses this principle to rectify the Hertzian oscillations, and applies the unidirectional currents of the oscillations themselves to operate a sensitive galvanometer or direct current instrument for quantitative measurements over short

[3] This patent of de Forest was subsequently held by the United States Circuit Court of Appeals to be void. See Appendix for the full text of this important judgment.

distances. When an independent source of electromotive force is applied in the manner I have described the action becomes quite different. It then operates as a *relay* to the Hertzian energy instead of merely rectifying this energy, so that it can be used directly to give the sense signal."

When, in the discussion, he was asked point blank by Mr. C. B. Ehret to state exactly wherein his audion differed from a Fleming valve, he could only repeat the assertion that his audion was a relay and the valve only a rectifier. He confidently asserted that the Fleming valve was useless in commercial wireless telegraphy.

[fol. 3118] He did not know that at that time the author's valve had been in practical use in radiotelegraphy in Great Britain for nearly eighteen months, and that it had been employed with a telephone, as a receiver, just in accordance with the diagram in his paper.

He was quite wrong in asserting that the form of Fleming valve he called an audion was a relay. Later on he did succeed in devising a form of valve, to be mentioned presently, which does or can act as a relay.

The instrument he described in this 1906 paper was simply a Fleming valve, and it did not operate as a true relay. If Dr. de Forest had studied a little more carefully the Royal Society paper of the author published in March, 1905, he would have seen there a series of characteristic curves delineated for one particular valve, showing the relation of thermionic current to potential difference of the plate and filament. These observations were made by inserting a battery in the external circuit joining the plate and filament, exactly as he did in his experiments, but employing a galvanometer as a current measurer. These curves give a full explanation of the action of the valve when used with such a boosting voltage and a telephone in the valve circuit. They show that for a particular voltage, or P.D., the thermionic current rises with great rapidity, and hence that when that critical steady auxiliary voltage is applied, a small additional voltage, such as is obtained by the superposition of an alternating E.M.F. on the steady E.M.F., may give rise to a large increase in the thermionic current.

Every electrical student was also aware long before 1906 that the telephone is sensitive only to *change of current*, and not to steady or unvarying current. Hence when a telephone is used in place of a galvanometer as a signal-recording

instrument it is an advantage to add such a boosting or additional steady E.M.F. in the valve circuit as will bring the effective P.D. between filament and plate to that point on the characteristic curve at which the thermionic current begins to rise rapidly. This, however, is not a true relay action.

Summing up the criticism with regard to this paper of de Forest, we may say that there were three facts which ought in fairness to have been brought to the notice of his audience at the time to enable them to judge of the novelty of this *new* receiver described to them. The first of these was that an exactly similar instrument—viz., an incandescent lamp having a plate or plates sealed into the bulb—had been patented, or patents applied for, as a detector in wireless telegraphy in Great Britain, the United States, German, France, Italy, and other countries by J. A. Fleming and Marconi's Wireless Telegraph Company months before the date when this paper was read by de Forest. Secondly, that it was not new to introduce a boosting or auxiliary voltage into the external or valve circuit; and thirdly, that Senatore Marconi had used such appliances supplied to him by the author of this book eighteen months before October, 1906, with a telephone as a receiver for wireless telegraphy.

There is no intention of suggesting any want of good faith or integrity on the part of Dr. Lee de Forest. He was at that date evidently quite sure that he had full right to [fol. 3119] make use of an incandescent electric lamp having a plate or plates sealed into the bulb as a detector in wireless telegraphy, and he was firmly convinced that his substitution of a battery-boosted telephone in place of a galvanometer was an important invention. Exactly ten years later he had these opinions corrected by the judgment of Judge Mayer, subsequently upheld by the Court of Appeals.

8. Shortly after reading this paper de Forest filed another application on October 25th, 1906, for a United States Patent No. 841,387, entitled "Device for Amplifying Feeble Electrical Currents," and in this we have the first indication of a genuine improvement.

The principal item in this specification is an incandescent lamp having in addition to the carbon or metal loop filament two metal plates sealed into the bulb. This in itself was not novel, because the author had shown in his Royal Society paper of February, 1905, *loc. cit.*, and in the first

edition of his book, *Principles of Electric Wave Telegraphy*, published April, 1906 (see Chapter VI) an oscillation valve with two such cold electrode plates.

Nevertheless, de Forest made a scheme of connections outside the valve as follows:

One of the plates and one terminal (the negative) of the filament in the bulb were connected to the aerial wire and earth of the wireless receiving set, whilst the second plate was connected with the positive terminal of the filament through a telephone and boosting battery. This arrangement was stated to work in virtue of the fact that the electrostatic attraction of the filament and plate connected to the wireless antenna would draw them together and so vary the distance between the filament and the second plate and thus alter the current through the telephone. It may be doubted very much whether any such attractions could be so controlled as to give rise to the required variations in the thermionic current flowing to the second plate to transmit intelligible signals. Moreover, the thermionic current is not sensibly altered by varying slightly the distance between a hot and cold electrode.

This patent specification, however, contained two claims (4 and 6) for a detector device for *amplifying* electric currents. The wording of them was as follows:

Claim 4.—In a device for amplifying electrical currents, an evacuated vessel, three electrodes, sealed within said vessel, means for heating one of said electrodes, a local receiving circuit, including two of said electrodes and means for passing the current to be amplified between one of the electrodes which is included in the receiving circuit and the third electrode.

Claim 6.—In a device for amplifying electrical currents, an evacuated vessel, a heated electrode and two non-heated electrodes seated within said vessel, the non-heated electrodes being unequally spaced with respect to said heated electrode, a local receiving circuit including said heated electrode and that one of the non-heated electrodes which has the greater separation from the heated electrode and means for passing the current to be amplified between the heated electrode and the other non-heated electrode.

[fol. 3120] As these claims constituted the first mention of what may be called a split cold electrode, the two parts be-

ing differently connected to the hot electrode, and as this formed the basis of a subsequent patent for a three-electrode amplifying valve of true relay action, the Marconi Wireless Telegraph Company of America, who were the plaintiffs in the action against the de Forest Radio Telephone and Telegraph Company in 1916, confessed judgment as to the two above claims, 4 and 6, in U. S. Patent No. 841,387, whilst the defendants withdrew issue on claim 5 of the above patent, which reads as follows:

Claim 5.—In a device for amplifying electrical currents an evacuated vessel enclosing a gaseous medium, means other than the received energy for maintaining said gaseous medium in a condition of molecular activity, means for impressing the current to be amplified upon said gaseous medium and a local receiving circuit having its electrodes within said vessel.

On January 29th, 1907, de Forest filed another application for a United States patent for an improvement in oscillation detectors of the type described in his United States Patents Nos. 824,637 and 836,070. These we have already seen are Fleming valves used with a telephone and boosting battery in series connected to the filament and the collecting plate or cold electrode.

The feature of the new specification, No. 879,532, is the introduction of a second cold electrode in the form of a grid placed between the incandescent filament and the other cold electrode plate. The scheme of connections is shown in Fig. 58.

Dr. de Forest gave no explanation in this specification as to the mode of action of the arrangement, but he states that the effect is to give louder sounds in the telephone used as a signal-receiving instrument. He may have been led to try this type of thermionic detector by his previous experiments, but at any rate the result was to furnish for the first time a modification of the thermionic valve which *can* act as a relay or amplifier under certain conditions.

The corresponding British patent to the above was applied for on January 21st, 1908, and is No. 1,427 of 1908; but under the Patents and Designs Act of 1907 the date claimed for this British patent is January 29th, 1907, being the date of application for the equivalent United States patent. This British patent of de Forest was, however, allowed

to lapse in 1911 and is therefore no longer in force. The name "audion" is now commonly applied in the United States of America to this grid and plate or three electrode thermionic detector. In Great Britain it is usually called an *amplifying valve*.

Discussions and controversies have taken place over the theory of its physical action, and it was the subject of the above mentioned hotly contested patent action in the United States in 1916 between Marconi's Wireless Telegraph Company of America as plaintiffs, owners of the United States Patent No. 803,684, of April 19th, 1905, issued November [fol. 3124] 7th, 1905, granted to John Ambrose Fleming, of London, England; and de Forest Radio Telephone and Telegraph Company and Lee de Forest, as defendants. The suit was brought for infringement of claims 1 and 37 in the above Fleming patent specification by the defendants.

The defendants made counter-claims on various claims of ten patents by Lee de Forest. At the opening of the trial plaintiffs confessed judgment as to claims 4 and 6 of United States Letters Patent No. 841,387, and defendants withdrew from issue claim 5 of the same patent. Plaintiffs also confessed judgment as to the claims in issue of United States Letters Patent No. 879,532, and defendants withdrew United States Letters Patent No. 837,901.

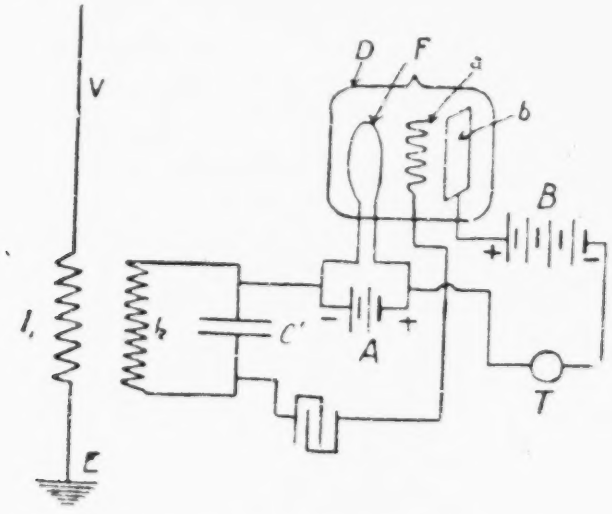

Fig. 3a. Lee de Forest's Three-Electrode Audion of 1907. D Glass Bulb. F Filament. a Grid. b Plate. A Filament Battery. B Plate Battery. T Telephone.

Of the counter-claim there remained in issue certain claims of seven patents—viz., Nos. 979,275, 867,876, 867,877,

...flow round B towards A in the upper portion and ... B to A in the lower portion. The electrostatic and electrodynamic E.M.Fs are therefore in opposite phases and oppose each other's action. If the secondary circuit is rotated through 90deg., through the first principal position, the direct action changes its sign, but not so the action of the waves, so that the two tend to strengthen each other. The same reasoning holds when the air space is at the lowest point of B.

Greater lengths of wire were then included between *m* and *n*, and it was found that the interference became gradually less marked, until with a length of 2·5 metres it disappeared entirely, the sparks being of equal length whether the normal was directed towards or away from P. When the length of wire between *m* and *n* was further increased, the distinction between the different quadrants reappeared, and with a length of 4 metres the disappearance of the sparks was fairly sharp. The disappearance, however, then took place (with the air space at the highest point) when the normal was directed away from P, the opposite direction to that in which the disappearance previously took place. With a still further increase in the length of the wire the interference reappeared and returned to its original direction with a length of 6 metres. These phenomena are clearly to be explained by the retardation of the waves in the wire, and show that here again the direction of action in the advancing waves changes its sign at intervals of about 2·8 metres.

For certain interference phenomena with the secondary circuit in the third principal position the rectilinear wire must be removed from its original position, and placed in the horizontal plane through C, either on the side of the plate A or of the plate A'. Practically it is sufficient to stretch the wire loosely and to fix it by means of an insulated clamp on each side of C alternately. It was found that when the wire was on the same side as the plate P the waves in it diminished the previous sparking, and when on the opposite side the sparking was increased, both results being unaffected by the position of the air space in the secondary circuit. Now it has been already pointed out that at the moment when the plate A has its maximum positive charge, and at which, therefore, the primary current begins to flow from A, the current at the first node of the rectilinear wire begins to flow away from the origin. The two currents therefore flow round C in the same direction when C lies between the rectilinear wire and A, and in opposite directions when the wire and A are on the same side of C. The fact that the position of the air space is indifferent confirms the conclusion formerly arrived at, that the direction of oscillation is that due to the electrodynamic E.M.F. These interferences are also changed in direction when the wire *m n*, 1 metre in length, is replaced by a wire 4 metres in length.

Dr. Hertz also resorted to obtaining interference phenomena ... the results of the second method was not in the least ... these results were of no special importance, except ... confirming the previous conclusions.

Interference Phenomena at Greater Distances. Interference ... produced with the secondary at greater distances than ... of the null point, but care must then be taken that ... action of the waves in the wire is of about the same magnitude as the direct action of the primary circuit through the air. This can be effected by increasing the distance between C and A.

Now if the velocity of propagation of the electrodynamic disturbances through the air is infinite, the interference will change its sign at every half wave length in the wire, that is to say, at intervals of about 2·8 metres. If the velocities of propagation through the air and through the wire are equal, the interference will be in the same direction at all distances. Finally, if the velocity of propagation through the air is finite, but different from the velocity in the wire, the interference will change its sign at intervals greater than 2·8 metres.

The interferences first investigated were those which occurred when the secondary circuit was rotated from the first into the second principal position, the air space being at the highest point. The distance of the secondary from the null point was observed by half metre stages from 0 up to 8 metres, and at each of these positions an observation was made of the effects ... the normal towards and away from P respectively. The points at which no difference in the sparking was observed in the two positions of the normal are marked 0 in the table below. Those in which the sparking was least, showing the existence of interference, when the normal was directed towards P are marked +, and those in which the sparking was least when the normal was directed away from P are marked −. The experiments were repeated with different lengths of wire *m n*, varying by steps of half a metre from ½ metre up to 6 metres. The first horizontal line in the table gives the distances in metres of the centre of the secondary circuit from the null point, while the first vertical line gives the lengths of the wire *m n*, also in metres.

600		+	+	+	0	0	−	−			−	0	0		+	+	

An inspection of this table shows, in the first place, that the changes of sign take place at longer intervals than 2·8 metres, and, in the second place, that the change of phase is more rapid in the neighbourhood of the origin than at a distance from it. As a variation in the velocity of propagation is very unlikely, this is probably due to the fact indicated by theory that the electrostatic E.M.F., which is more powerful than the electrodynamic E.M.F. in the neighbourhood of the primary oscillation, has a greater velocity of propagation than the latter.

In order to obtain a definite proof of the existence of similar phenomena at greater distances Dr. Hertz continued the observations, in the case of three of the lengths *m n*, up to a distance of 12 metres, and the result is given in the table below.

TABLE II.

	0	1	2	3	4	5	6	7	8	9	10	11	12
100	−	0	−	−	0	0	0	−	−	−	−	−	0
250	0	−	−	0	+	−	0	0	0	0	−	−	−
400	−	0	−	−	0	0	−				0	0	0

If we make the assumption that at the greater distance it is only the E.M.F. of induction which produces any effect, the experiments would show that the interference of the waves excited by the E.M.F. of induction with the original waves in the wire changes its sign only at intervals of about seven metres.

In order to investigate the E.M.F. of induction close to the primary oscillation, where the results are of special importance, Dr. Hertz made use of the interferences which were obtained when the secondary circuit was in the third principal position, and the air space was rotated through 90deg. from the base line. The direction of the interference at the null point, which has already been considered, was taken as negative, the interference being considered positive when it was produced by the passage of waves on the side of C remote from P, which makes the signs correspond with those of the previous experiments. It must be borne in mind that the direction of the resultant E.M.F. at the null point is opposed to that of the E.M.F. of induction, and therefore the first table would have begun with a negative sign if the electrostatic E.M.F. could have been eliminated. The present experiments showed that up to a distance of three metres interference continued to occur, and always of the same sign as at the null point. It was unfortunately impossible to extend these observations to a greater distance than four metres, on account of the feebleness of the sparks, but the results obtained were sufficient to give distinct evidence of a finite velocity of propagation of the E.M.F. of induction. These observations, like the former ones,

were repeated with various lengths of the wire as a in order to exhibit the variation in phase, and the results obtained are given in the table below :—

TABLE III.

	0	1	2	3	4
100	-	-	-	-	0
150	-	-	0	0	0
200	0	0	0	+	+
250	0	+	+	+	+
300	+	+	+	+	+
350	+	+	+	+	0
400	+	+	+	+	0
450	+	+	+	0	0
500	+	+	0	0	0
550	+	0	0	0	-
600	0	-	-	-	-

which shows that as the distance increases the phase of the interference changes in such a manner that a reversal of sign takes place at intervals of from seven to eight metres. This result is further confirmed by comparing the results of Table III. with the results for greater distances given in Table II., for in the former series the effect of the electrostatic E.M.F. is eliminated owing to the special position of the secondary circuit, while in the former it becomes insensible at the greater distances owing to its rapid decrease with increasing distance. We should therefore expect the results given in the first table for distances beyond four metres to follow without a break the results given in Table III. for distances up to four metres. This was found to be the case, as is evident from inspection of Tables II. and III.

To show this more clearly the signs of the interference of the waves, due to the electro-dynamic E.M.F., with the waves in the wire, are collected together in Table IV., the first four columns of which are taken from Table III., and the remaining columns from Table II.

TABLE IV.

	0	1	2	3	4	5	6	7	8	9	10	11	12
100	-	-	-	-	0	0	0	+	+	+	+	+	0
250	0	+	+	+	+	+	0	0	0	0	-	-	-
400	+	+	+	+	0	0	-	-	-	-	0	0	0

From the results given in this table the author draws the following conclusions :—

(1) The interference does not change its sign at intervals of 2·8 metres. The electro-dynamic actions are therefore not propagated with an infinite velocity.

(2) The interference is not in the same phase at all points. Therefore the electro-dynamic actions are not propagated through air with the same velocity as electric waves in wires.

(3) A gradual retardation of the waves in the wire has the effect of displacing a given phase of the interference towards the origin of the waves. The velocity of propagation through the air is therefore greater than through a wire.

(4) The sign of the interference is reversed at intervals of 7·5 metres, and therefore in traversing this distance an electro-dynamic wave gains one length of the waves in the wire.

Thus, while the former travels 7·5 metres, the latter travels 7·5 – 2·8 = 4·7 metres, and therefore the ratio of the velocities is 75 : 47, which gives for the half-wave length of the electro-dynamic action 2·8 × 75/47 = 4·5 metres. Since this distance is traversed in 1·4 hundred-millionths of a second, the absolute velocity of propagation through the air must be 320,000 kilometres per second. This result can only be considered reliable as far as its order is concerned; but its true value can hardly exceed half as much again, or be less than two-thirds of this amount. In order to obtain a more accurate determination of the true value it will be necessary to determine the velocity of electric waves in wires with greater exactness.

It does not necessarily follow from the fact that in the immediate neighbourhood of the primary oscillation the interference changes its sign after an interval of 2·8 metres that the velocity of propagation of the electrostatic action is infinite, for such a conclusion would rest upon a single change of sign, which might, moreover, be explained, independently of any change of phase, by a change in the sign of the amplitude of the resultant force at a certain distance from the primary oscillation. Quite independently, however, of any knowledge of the velocity of propagation of electrostatic actions, there exist definite proofs that the rates of propagation of electrostatic and electro-dynamic E.M.F.s are unequal.

In the first place the total force does not vanish at any point on the base line. Now, near the primary the electrostatic E.M.F. is the greater, while the electro-dynamic E.M.F. is the greater at greater distances. There must, therefore, be some point at which they are equal, and since they do not balance they must take different times to reach this point.

In the second place, the existence of points at which the direction of the resultant E.M.F. becomes indeterminate does not seem capable of explanation, except on the supposition that the electrostatic and electro-dynamic components perpendicular to each other are in appreciably different phases, and, therefore, do not compound into a rectilinear oscillation in a fixed direction. The fact that the two components of the resultant are propagated with different velocities is of considerable importance, in that it gives an independent proof that one of them at any rate must have a finite velocity of propagation.

THE TESLA MOTOR AND WESTINGHOUSE STATION SWITCH-BOARD ARRANGEMENT.

As announced some time ago, work has been actively prosecuted, says the *Electrical World*, by the Westinghouse Electric Company in the construction of an alternating-current motor by which the value of the alternating system as a method of power distribution is largely increased. This new motor, which is illustrated in the

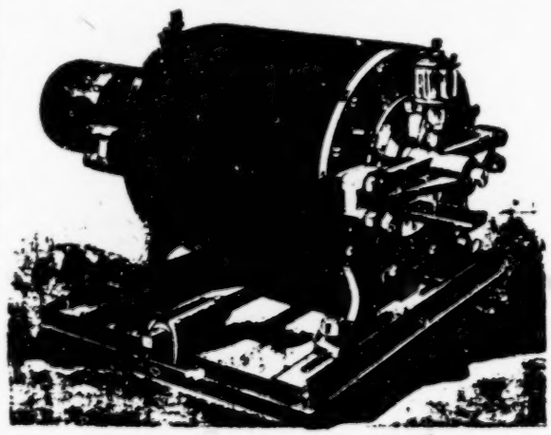

FIG. 1.

The New Westinghouse Alternating Current Motor.

accompanying illustration (Fig. 1), is based on the method of electro-dynamic rotation devised by Mr. Nikola Tesla,* and is so constructed that no commutator or contact brush of any kind is required, the armature being without any external electrical connection, and the rotative effort being exerted entirely from the changing polarity of the field-magnets.

As will be seen, the motor consists of a series of field-magnets built up of laminated sheet iron and wound with two sets of coils, the ends of which are connected to the two binding posts shown. These binding posts form the only connection with the regular lighting circuits, with the addition of a single return wire. By the aid of this return wire two alternating currents are sent through the field of the motor at the same time, the pulsations of the two currents being equal in strength, but the one lagging a quarter phase behind the other in the two sets of field coils respectively.

* See *The Electrician*, June 15, 1888.

This gives us the value of the inverse induced current at any time during the breaking of the primary. Expand the above expression by the exponential theorem and it becomes

$$i = \frac{M}{L} I - \frac{M}{L^2} \frac{R \delta t}{1 \cdot 2} + \frac{M}{L^3} \frac{R^2 \delta t^2}{1 \cdot 2 \cdot 3} - \text{etc.}$$

At the instant when the removal of lines of force or the cessation of the induction through the secondary takes place the impressed electromotive force ceases and the secondary current begins to die away. If we suppose the "break" of the primary to be very sudden, δt becomes practically zero, and we have

$$i = \frac{M}{L} I ;$$

that is to say, the secondary current starts with a value equal to $\frac{M}{L}$ of that of the steady primary.

The state of things in the secondary circuit immediately after the break of the primary is, then, this: the electromotive impulse due to stoppage of the primary has generated a current of initial value $\frac{M}{L} I$ in the secondary, but there is no impressed electromotive in the secondary circuit. If at any instant after the break the current in the secondary circuit is i, the law of decay of this current is expressed by the equation

$$L \frac{di}{dt} + R i = 0.$$

The solution of this is

$$i = C e^{-\frac{R}{L} t}$$

and the constant C is found from the condition that when $t = 0$, $i = \frac{M}{L} I$. Hence we have

$$i = \frac{M}{L} I e^{-\frac{R}{L} t} \quad \ldots \ldots \quad (7)$$

This gives us the value of the direct or "break" induced current in the secondary at any instant after the break of the

FIG. 10.

primary. Graphically, this may be represented by a curve, such as that in Fig. 10. During the time O T in which the primary is being broken the induced electromotive force is creating an induced current, the rising strength of which is represented by the rise O P. The time occupied by the break is O T. As O T is diminished in value, the magnitude of the maximum ordinate P T, approximates to $\frac{M}{L} I$, and this is the initial value of the inverse secondary current when the break is very sudden. After the break the current decays away along a path represented by P Q, and becomes zero only after an infinite time.

The whole quantity of the induced current is obtained by integrating equation (7) with respect to the time from zero to infinity, thus

$$\int_0^\infty i \, dt = \int_0^\infty \frac{M}{L} I e^{-\frac{R}{L} t} = \frac{M I}{R}$$

We see, then, that both the maximum value and whole quantity of the direct secondary current are proportional to the coefficient of mutual induction and to the strength of the primary current, and, moreover, that the whole quantity of electricity set in motion in a secondary circuit of total resistance R by suddenly removing from it M I lines of force is equal to the quotient of number of lines removed by the total resistance of the secondary circuit.

If the induced current is sent through a galvanometer the indications are proportional to the magnitude of $\frac{M I}{R}$. If, however, the induced current is employed to magnetise steel needles, the magnetisation acquired is dependent upon the magnitude of $\frac{M I}{L}$, and is therefore greater in proportion as the coefficient of self-induction of the secondary circuit is less. Lord Rayleigh has pointed this out,* and shown by experiment that within certain limits the magnetising effect of the break-induced current on steel needles is *greater* the smaller the number of turns of which the secondary consists, the opposite being, of course, true of the galvanometer. The galvanometer takes account of the induced current as a whole; whilst the magnetising power depends mainly on the magnitude of the current at the first moment of its formation, without regard to the time which it takes to subside.

(To be continued.)

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY O. W. DE TUNZELMANN, B.SC.

(Concluded from page 18.)

The latest researches of Dr. Hertz on electrical oscillations of which accounts have been published at present are described in a Paper "On Electro-Dynamic Waves in Air, and their Reflection," in Wiedemann's *Annalen*, Vol. XXXIV., p. 609. The author had been endeavouring to find a more striking and direct proof of the finite velocity of propagation of electro-dynamic waves than those which he had hitherto given, for, though these are quite sufficient to establish the fact, they can only be properly appreciated by one who has obtained a grasp of the results of the entire series of researches.

In many of the experiments which have been described Dr. Hertz had noticed the appearance of sparks at points in the secondary conductor, where it was clear from geometrical considerations that they could not be due to direct action, and it was observed that this occurred chiefly in the neighbourhood of solid obstacles. It was found, moreover, that in most positions of the secondary conductor the feeble sparks produced at a great distance from the primary became considerably stronger in the vicinity of a solid wall, but disappeared with considerable suddenness quite close to the wall. The most obvious explanation of these experiments was that the waves of inductive action were reflected from the wall and interfered with the direct waves, especially as it was found that the phenomena became more distinct when the circumstances were such as to favour reflection to the greatest possible extent. Dr. Hertz therefore determined upon a thorough investigation of the phenomena.

The experiments were made in the Physical Lecture Theatre, which is 15 metres in length, 14 metres in width, and 6 metres in height. Two rows of iron columns, running parallel to the sides of the room, would collectively act almost like a solid wall towards electro-dynamic action, so that the available width of the room was only 8·5 metres. All pendant gas fittings were removed, and the room left empty, with the exception of wooden tables and forms, which would not exert any appreciable disturbing effect. The end wall, from which the waves were to be reflected, was of solid sandstone, with two

* *Phil. Mag.*, Ser. 4, Vol. XXXIX., 1870, p. 429.

3570

doors in it, and the numerous gas pipes attached to it gave it, to a certain extent, the character of a conducting surface, and this was increased by fastening to it a sheet of zinc 4 metres high and 2 metres broad, connected by wires to the gas pipes and a neighbouring water pipe. Special care was taken to provide an escape for the electricity at the upper and lower extremities of the zinc plate, where a certain accumulation of electricity was to be expected.

The primary conductor was the same that was employed in the experiments described in my last Paper, and was placed at a distance of 13 metres from the zinc plate, and, therefore, two metres from the wall at the other end of the room. The connecting wire was placed vertically, so that the E.M.F.s to be considered increased and diminished in a vertical direction. The centre of the primary conductor was 2.5 metres above the floor of the room, which left a clear space for the observations above the tables and benches. The point of intersection of the reflecting surface with the perpendicular from the centre of the primary conductor will be called the point of incidence, and the experiments were limited to the neighbourhood of this point, as the investigation of waves striking the wall at a considerable angle would be complicated by the differences in their polarisation. The plane of vibration was therefore parallel to the reflecting surface, and the plane of the waves was perpendicular to it, and passed through the point of incidence.

The secondary conductor consisted of the circle of 35 centimetres radius, which has been already described. It was movable about an axis through its centre perpendicular to its plane, and the axis itself was movable in a horizontal plane about a vertical axis. In most of the experiments the secondary conductor was held

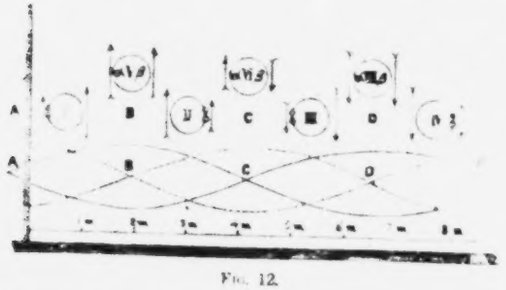

FIG. 12.

in the hand by its insulating wooden support, as this was the most convenient way of bringing it into the various positions required. The results of these experiments, however, had to be checked by observations made with the observer at a greater distance from the secondary, as the neighbourhood of his body exerted a slight influence upon the phenomena. The sparks were distinct enough to be observed at a distance of several metres when the room was darkened, but when the room remained light they were practically invisible even when the observer was quite close to the secondary.

When the centre of the secondary was placed in the line of incidence and with its plane in the plane of vibration, and the air space was turned first towards the reflecting wall and then away from it, a considerable difference was generally observed in the strength of the sparks in the two positions. At a distance of about 0.8 metre from the wall the sparks were much stronger when the air space was directed towards the wall, and its length could be adjusted so that while there was a steady stream of sparks when in this position, they disappeared entirely when the air space was directed away from the wall. These phenomena were reversed at a distance of 3 metres, and recurred, as in the first case, at a distance of 5.5 metres. At a distance of 8 metres the sparks were stronger when the air space was turned away from the wall, as at the distance of 3 metres, but the difference was not so well marked. When the distance was increased beyond 8 metres no further reversal took place, owing to the increase in the direct effect of the primary oscillation and the complicated distribution of the E.M.F. in its neighbourhood.

The positions I., II., III., and IV. (Fig. 12) of the secondary circle are those in which the sparks were strongest, the distance from the wall being shown by the horizontal scale at the foot. When the secondary circle was in the positions V., VI., and VII., the sparks were equally strong in both positions of the air space, and quite close to the wall the difference between the sparking in the two positions again diminished. Therefore the points A, B, C, D in the diagram may in a certain sense be regarded as nodes. The distance between two of these points must be, however, be taken as the half wave length, for at all the electrical motions changed their directions on passing through one of these points the phenomena observed in the secondary circuit would be repeated without variation, since the direction of oscillation in the air space is indifferent.

The conclusion to be drawn from the experiments is that on passing any one of these points part of the action is reversed, while another part is not. The experimental results, however, warrant the assumption that twice the distance between two of these points is equal to the half wave length, and when this assumption is made the phenomena can be fully explained.

For, suppose a wave of E.M.F., with oscillations in a vertical direction, to impinge upon the wall, and to be reflected with only slightly diminished intensity, thus giving rise to stationary waves. If the wall were a perfect conductor, a node would necessarily be formed in its surface, for at the boundary and in the interior of a perfect conductor the E.M.F. must be intrinsically small. The wall cannot, however, be considered as a perfect conductor, for it was not metallic throughout, and the portion which was metallic was not of any great extent. The E.M.F. would therefore have a finite value at its surface, and would be in the direction of the impinging waves. The node which in the case of perfect conductivity would occur at the surface of the wall, would, therefore, actually be situated a little behind it, as shown at A in the diagram. If, then, twice the distance A B—that is to say, the distance A C—is half the wave length the steady waves will be as represented by the continuous lines in Fig. 12. The E.M.F.s acting on each side of the circles, in the positions I., II., III., and IV., will therefore at a given moment be represented in magnitude and direction by the arrows on each side of them in the diagram. If, therefore, in the neighbourhood of a node the air space is turned towards the node the strongest E.M.F. in the circle will act under more favourable conditions against a weaker one under less favourable conditions. If, however, the air space is turned away from the node, the stronger E.M.F. acts under less favourable conditions against a weaker one under more favourable conditions. In the latter case the resultant action must be less than in the former, whichever of the two E.M.F.s has the greater effect, which explains the change of sign of the phenomenon at each quarter wave length.

This explanation is further confirmed by the consideration that if it is the true one the change of sign at the points B and D must take place in quite a different manner from that of the point C. The E.M.F.s acting on the secondary circle, in the positions V., VI., and VII., are shown by the corresponding arrows, and it is clear that in the positions B and D, if the air space is turned from one side to the other, the vibration will change its direction round the circle, and, therefore, the sparking must during the rotation vanish either once or an uneven number of times. In the position C, however, the direction of vibration remains unaltered, and therefore the sparks must disappear an even number of times, or not at all.

The experiments showed that at B and D the sparking diminished as the air space revolved from α, vanished at the highest point, and again attained its original value at the point β. At C, on the other hand, the sparking continued throughout the rotation, being a little stronger at the highest and lowest points. If, then, there is any change of sign in the position C, it must occur with very much smaller displacement than in the other positions, so that in any case there is a distinction such as required between this and the other two cases.

Another very direct proof of the truth of Dr. Hertz's hypothesis of the nature of the waves was obtained. If the secondary circle lies in the plane of the waves instead of in the plane of vibration, the E.M.F. must be equal at all points of the circle, and for a given position of the air space the sparking must be directly proportional to its intensity. When the experiment was made it was found, as expected, that at all

3127

3571

distances the sparking vanished at the highest and lowest points of the circle, and attained a maximum value at the points in the horizontal plane through the point of incidence.

The air space was then placed at such a point and close to the wall and was then moved slowly away from the wall, when it was found that while there was no sparking quite close to the metal plate, it began at a very small distance from it, rapidly increased, reached a maximum at the point B, and then diminished again. At C the sparking again became excessively feeble, and increased as the circle was moved still further away. The sparking continued steadily to increase after this, as the motion of the circle was continued in the same direction, owing, as before, to the direct action of the primary oscillation.

The curves shown by the continuous lines in Fig. 12 were obtained from the results of these experiments, the ordinates representing the intensity of the sparks at the distances represented by the corresponding abscissæ.

The existence in the electrical waves of nodes at A and C, and of loops at B and D, is fully established by the experiments which have been described; but in another sense the points B and D may be regarded as nodes, for they are the nodal points of a stationary wave of magnetic induction which, according to theory, accompanies the electrical wave and lags a quarter wave-length behind it.

This can easily be shown to follow from the experiments, for when the secondary circle is placed in the plane of vibration with the air space at its highest point, there will be no sparking if the E.M.F. is uniform throughout the space occupied by the secondary. This can only take place if the E.M.F. varies from point to point of the circle, and if its integral round the circle differs from zero. This integral is proportional to the number of magnetic lines of force passing backwards and forwards across the circle, and the intensity of the sparks may be considered as giving a measure of the magnetic induction, which is perpendicular to the plane of the circle. Now in this position vigorous sparking was observed close to the wall, diminishing rapidly to zero as the point B was approached, then increasing to a maximum at C, falling to a well-marked minimum at D, and finally increasing continuously as the secondary approached still nearer to the primary. If the intensities of these sparks are taken as ordinates, positive and negative, and the distances from the wall as abscissæ, the curve shown by the dotted lines in Fig. 12 is obtained, which therefore represents the magnetic waves.

The phenomena observed in the first series of experiments described in this Paper may therefore be regarded as due to the resultant electric and magnetic actions. The former changes sign at A and C, the latter at B and D, so that at each of these points one part of the action changes sign, while the other does not, and therefore the resultant action which is their product must change sign at each of these points, as was found to be the case.

When the secondary circle was in the plane of vibration the sparking in the vicinity of the wall was observed to be a maximum on the side towards the wall, and a minimum at the opposite side, and as the circle was turned from one position to the other there was found to be no point at which the sparks disappeared. As the distance from the wall was increased the sparks on the remote side gradually became weaker, and vanished at a distance of 1·08 metre from the wall. When the circle was carried further in the same direction the sparks appeared again on the side remote from the wall, but were always weaker than on the side next to it; the sparking, however, no longer passed from a maximum to a minimum merely, but vanished during the rotation once in the upper and once in the lower half of the circle. The two null points gradually receded from their original coincident positions, until at the point B they occurred at the highest and lowest points of the circle. As the circle was moved further in the same direction, the null points passed over to the side next to the wall, and approached each other again, until when the centre was at a distance of 2·35 metres from the wall the two null points were again coincident. B must be exactly half-way between this point and the similar point previously observed, which gives 1·72 metre as the distance of B from the wall, a result which agrees, within a few centimetres, with that obtained by direct observation. Moving further in the direction of C, the sparking at different points of the circle became more nearly equal, until at C it was exactly so. In this position there was no null point, and as the distance was further increased the phenomena recurred in the same order as before.

Dr. Hertz found that the position of C could be determined within a few centimetres, the determinations of its distance from the wall varying from 4·10 to 4·15 metres; he gives its most probable value as 4·12 metres. The point B could not be observed with any exactness, the direct determinations varying from 6 to 7·5 metres as its distance from the wall. It could, however, be determined indirectly, for the distance between B and C being found to be 2·4 metres, taking this as the true value, A must have been 0·68 metre behind the surface of the wall, and 6·52 metres in front of it. The half-wave length would be 4·8 metres, and by an indirect method it was found to be 4·5 metres, so that the two results agree fairly well. Taking the mean of these as the true value, and the velocity of light as the velocity of propagation, gives as the vibration period of the apparatus 1·55 hundred millionths of a second, instead of 1·4 hundred millionths, which was the theoretically calculated value.

A second series of experiments were made with a smaller apparatus, and though the measurements could not be made with as much exactness as those already described, the results showed clearly that the position of the nodes depends only on the dimensions of the conductors and not on the material of the wall.

Dr. Hertz states that after some practice he succeeded in obtaining indications of reflection from each of the walls. He was also able to obtain distinct evidence of reflection from one of the iron columns in the room, and of the existence of electrodynamic shadows on the side of the column remote from the primary.

In the preceding experiments the secondary conductor was always placed between the wall and the primary conductor—that is to say, in a space in which the direct and reflected rays were travelling in opposite directions, and gave rise to stationary waves by their interference.

He next placed the primary conductor between the wall and the secondary, so that the latter was in a space in which the direct and reflected waves were travelling in the same direction. This would necessarily give rise to a resultant wave, the intensity of which would depend on the difference in phase of the two interfering waves. In order to obtain distinct results it was necessary that the two waves should be of approximately equal intensities, and therefore the distance of the primary from the wall had to be small in comparison with the extent of the latter, and also in comparison with its distance from the secondary.

To fulfil these conditions the secondary was placed at a distance of 14 metres from the reflecting wall, and, therefore, about 1 metre from the opposite one, with its plane in the plane of vibration, and its air space directed towards the nearest wall, in order to make the conditions as favourable as possible for the production of sparks. The primary was placed parallel to its former position, and at a perpendicular distance of about 30 centimetres from the centre of the reflecting metallic plate. The sparks observed in the secondary were then very feeble, and the air space was increased until they disappeared. The primary conductor was then gradually moved away from the wall, when isolated sparks were soon observed in the secondary, passing into a continuous stream when the primary was between 1·5 and 2 metres from the wall—that is, at the point B. This might have been supposed to be due to the decrease in the distance between the two conductors, except that as the primary conductor was moved still further from the wall the sparking again diminished, and disappeared when the primary was at the point C. After passing this point the sparking continually increased as the primary approached nearer to the secondary. These experiments were found to be easy to repeat with smaller apparatus, and the results obtained confirmed the former conclusion, that the position of the nodes depends only on the dimensions of the conductor, and not on the material of the reflecting wall.

Dr. Hertz points out that these phenomena, which are exactly analogous to the acoustical experiment of approaching a vibrat-

3572

ing tuning fork to a wall, when the sound is weakened in certain positions and strengthened in others, and also to the optical phenomena illustrated in Lloyd's form of Fresnel's mirror experiments; and as these are accepted as arguments tending to prove that sound and light are due to vibration, his investigations give a strong support to the theory that the propagation of electro-magnetic induction also takes place by means of waves. They, therefore, afford a confirmation of the Faraday-Maxwell theory of electrical action. He points out, however, that Maxwell's, in common with other electrical theories, leads to the conclusion that electricity travels through wires with the velocity of light, a conclusion which his experiments show to be untrue. He states that he intends to make this contradiction between theory and experiment the subject of further investigation.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

SECTION II.—ELECTRO-MAGNETIC FIELDS.

(*Continued from page 821, Vol. XXI.*)

135. *Electro-Magnetisation of Annealed Iron Wire.*—In order to observe the magnetisation of a piece of iron when there is practically no demagnetising effect from its own poles, it has been stated that a rod or wire must be selected whose length is at least 300 times its diameter. Now, if the magnetic moment is measured by either of the two methods of Gauss already detailed (para. 125), the iron wire tested must be very small in diameter, as it is not convenient to test a very long wire by these methods. And the strength of pole developed in a wire of small diameter is necessarily very small even when the iron has acquired a high magnetisation in consequence of

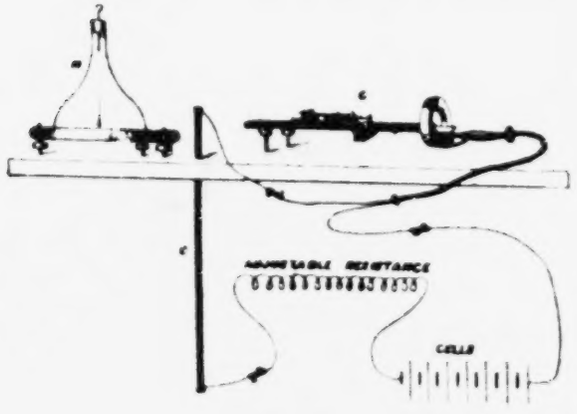

Fig. 116.

which the magnetometer can only be deflected to very small angles. With a light mirror attached to the needle, the amplitude of the deflections can be considerably increased by a ray of light reflected from the mirror on to a screen, and in this manner very small movements of the needle can be accurately observed. We are here, however, employing a magnetometer without a mirror attachment, and it is therefore advisable to arrange matters so that the needle is deflected to a considerable angle, say to 30 deg. or 60 deg., when the iron is near its highest magnetisation. The intermediate deflections can then be read with ease and accuracy. This may be effected conveniently by using a long core and placing it vertically, as shown at C (Fig. 116). As large a diameter as No. 11 B.W.G. iron wire may be used for a core 3ft. long, and yet be over the necessary ratio of length to diameter. This gives sufficient sectional area of iron to develop, at high magnetisations, enough strength of pole to strongly deflect the needle, the top end of the core being within 20 centimetres from the needle. In this diagram, C is the magnetising coil wound round a brass tube, and fixed vertically by passing it through a hole in the table. The iron wire core of the same length as the tube should slip easily into it, and the upper end of the latter be fixed a little above the level of the magnetometer needle, in order that the pole which is formed at a little distance from the end, may set itself nearly in a horizontal line with the needle. As the iron becomes more magnetised the poles move up more to the ends, but are always some slight distance off, even when most strongly magnetised. By this method the upper pole acts powerfully on the needle, and with a long core the action of the lower pole is very feeble. If we neglect the action of the lower pole, the intensity of field at the needle placed R centimetres away from the upper pole, is

$$\frac{m}{R^2} \text{ C.G.S. units,}$$

where m is the strength of pole (see paras. 108 and 109). But where accuracy is required the action of the lower pole must be taken into account. Taking the point of p (Fig. 117) as the centre of the magnetometer needle and SN as the magnetised core, it will be seen that the lower pole (R centimetres from p) would repel a unit north pole at p with a force of

$$\frac{m}{R'^2} \text{ dynes.}$$

But this force is in an oblique direction, and the needle moving in a horizontal plane is only influenced by horizontal forces. It is therefore only the horizontal component of the above force that we have to deal with. Resolving by the parallelogram of forces we have by similar triangles

$$\frac{\text{horizontal component}}{\frac{m}{R'^2}} = \frac{x}{R'}$$

whence the horizontal force $= \frac{mx}{R'^3}$ dynes.

Fig. 117.

The resultant force f at the needle is then the difference between the forces due to each pole, viz.

$$\frac{m}{R^2} - \frac{mx}{R'^3} \text{ dynes.}$$

Now, the force in dynes on unit pole at a point is the same thing as the intensity of field at that point, and the value of f above value of f represents the strength of field at the needle centre due to both poles of the core. This field deflects the needle at right angles to the earth's horizontal field H, and therefore (by para. 119)

$$f = H \tan \alpha,$$

where α is the angular deflection of needle. (Glancing at the figure it will be noticed that the coil of the magnetometer needle is viewed, the earth's meridian being supposed to be at right angles to the plane of the paper, and the magnetising coil C being placed east or west of the needle.

35773

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY DR. W. DE GUNZBURG, PH.D.

(Continued from page 758.)

It was shown in the experiments described in my last Paper that when variable electrical forces act in the interior of dielectrics of specific inductive capacity not equal to unity, the corresponding electrodisplacements produce electrodynamic effects (see paper "On the Velocity of Propagation of Electro Dynamic Actions," in Wiedemann's *Annalen*, Vol. XXXIV., p. 551). Dr. Hertz shows that similar actions take place in the air, which proves, as was previously pointed out, that electrodynamic actions must be propagated with a finite velocity.

The method of investigation was to excite electrical oscillations in a rectilinear conductor in the same manner as in former experiments, and then to produce effects in a secondary conductor by exciting electrical oscillations in it by means of those in the rectilinear conductor, and at the same time by the primary conductor acting through the intervening space. This distance was gradually increased, when it was found that the phase of the vibrations at a distance from the primary lagged behind those in its immediate neighbourhood, showing that the action is propagated with a finite velocity, which was found to be greater than the velocity of propagation of electrical waves in wires in the ratio of about 15 to 25, so that the former is of the same order as the velocity of light. Dr. Hertz was unable to obtain any evidence with respect to the velocity of propagation of electrostatic actions.

Fig. 11.

The primary conductor A A (fig. 11) consisted of a pair of square brass plates with sides 40 centimetres in length, connected by a copper wire 30 centimetres in length, at the middle point of which was an air space, across which sparks were made to pass by means of powerful discharges from the induction coil. The conductor was fixed at a height of 2 metres above the base plate of the coil with its plates vertical and the connecting wire horizontal. A straight line, drawn horizontally through the air space of the primary and perpendicular to the direction of the primary oscillation will be called the base line, a point in this situated at a distance of 1 centimetre from the air space will be referred to as the base point.

The experiments were made in a large lecture room with nothing near the apparatus for a distance of 12 metres from the primary conductor. The room was darkened during the experiments.

The secondary conductor consisted of a circular wire of 35 centimetres radius, and a circular piece of wire D with a micrometer screw. The primary and secondary air spaces were both capable of adjustment by means of micrometer screws. With the secondary conductor so arranged that the plane of the ball end was parallel to the base line, and at a distance of 1 centimetre from it, sparks were observed in the micrometer air space of the secondary, and on account of self-induction. It is doubtful whether the ordinary theory of electrical oscillations would hold for circuits of such dimensions as those of the experiments, but as it gives correct numerical results in the case of Leyden jar discharges, it may be expected to be correct as far as the order of the results is concerned. When the centre of the secondary lies in the base line, and its plane coincides with the vertical plane through the base line, no sparks are observed in the secondary, the E.M.F. being everywhere perpendicular to the direction of the wire. This will be referred to as "the first principal position" of the secondary. When the plane of the secondary is vertical and perpendicular to the base line, the centre still being in the base line, the secondary will be said to be in the "second principal position." Sparking then occurs in the secondary, and its air space is either above or below the base line, but not when it is exactly through the base line, but not when it is exactly through the base line, but not when it is exactly through

[illegible] waves in the rectilinear wire were of the [illegible] as that of the primary oscillations, as was [illegible] their being shown to be in unison with each [illegible] secondary conductors previously described. [illegible] of stationary waves showed that the waves [illegible] wire were of a steady character in space as [illegible] time. The nodal points were determined in the [illegible] manner. The further end of the wire was left free, [illegible] secondary conductor was brought near to it, in such [illegible] that the wire lay in its plane, and had the air space [illegible] it. As the secondary was moved along the [illegible] of no sparking were observed to recur periodically. [illegible] from the point *a* to the first of these was [illegible], and the length of the wire made equal to a multiple [illegible] distance. The experiments were then repeated, and it [illegible] that the nodal points occurred at approximately [illegible] intervals along the wire.

The nodes could also be distinguished from the loops in [illegible] ways. The secondary conductor was brought near to [illegible] with its plane perpendicular to it, and with its air [illegible] neither directed completely towards the wire nor com- [illegible] away from it, but in an intermediate position, so as to [illegible] E.M.F.s perpendicular to the wire. Sparks were then [illegible] at the nodes, while they disappeared at the loops. [illegible] sparks were taken from the rectilinear wire by means [illegible] insulated conductor, they were found to be stronger at [illegible] nodes than at the loops; the difference, however, was [illegible] and was, indeed, scarcely distinguishable unless the [illegible] of the nodes and loops was previously known. The [illegible] that this and other similar methods do not give a well [illegible] result lies in the fact that irregular oscillations are [illegible] upon the waves considered; the regular waves, however, can be picked out by means of the secondary, just [illegible] definite notes are picked out by means of a Helmholtz reso- [illegible]. If the wire is severed at a node, no effect is produced [illegible] the waves in the portion of wire next to the origin, but [illegible] the severed portion of wire is left in its place, the waves [illegible] to be propagated through it, though with somewhat [illegible] strength.

The possibility of measuring the wave lengths leads to [illegible] applications. If the copper wire hitherto used is re- [illegible] by one of different diameter, or by a wire of some other [illegible], the nodal points retain their position unchanged. It [illegible] from this that the velocity of propagation in a wire [illegible] a definite value independent of its dimensions and material. [illegible] iron wires offer no exception to this, showing that the [illegible] susceptibility of iron does not play any part in the [illegible] of such rapid motions. It would be interesting to investi- [illegible] the behaviour of electrolytes in this respect. In their case we should expect a smaller velocity of propagation, because the electrical motions are accompanied by motions of the mole- [illegible] carrying the electric charges. It was found that no [illegible] propagation of the waves took place through a tube 10 milli- [illegible] metres in diameter, filled with a solution of sulphate of copper; but this may have been due to the resistance being too high. By the measurement of wave lengths the relative vibration periods of different primary conductors can be determined, and it therefore becomes possible to compare in this manner the [illegible] vibration periods of plates, spheres, ellipsoids, &c.

In the experiments made by Dr. Hertz nodes were very distinctly produced when the wire was severed at a distance of either 8 metres or 5·5 metres from the null point of the base [illegible]. In the first case the nodes occurred at distances from the null point of −0·2 metre, 2·3 metres, 5·1 metres, and [illegible] metres, and in the latter case at distances of −0·1 metre, [illegible] metres, and 5·5 metres. It appears, therefore, that the [illegible] wave length in a free wire cannot differ much from [illegible] metres. The fact that the wave lengths nearest to P were somewhat smaller was to be expected from the influence of the plates and of the curvature of the wire. This wave length, with a period of 1·4 hundred millionths of a second, gives 300,000 kilometres per second for the velocity of propagation of electrical waves in wires. Fizeau and Gounelle (Poggendorff's *Annalen*, Vol. LXXX., p. 158, 1850) obtained for the velocity in iron wires 100,000 kilometres per second, and 200,000 in copper wires. W. Siemens (Poggendorff's *Annalen*, Vol. CLVII., p. 309, 1876), by the aid of Leyden jar discharges, obtained a velocity of from 200,000 to 260,000 kilometres per second in iron wires. Dr. Hertz's result is very nearly the mean of these, from which we may conclude that the order at any rate, of the vibration period as calculated by him is correct. The value obtained cannot be regarded, independently of its agreement with experimental results otherwise obtained, as a fresh determination of the velocity, since it rests upon a theory which is open to doubt.

(To be continued.)

THE ELECTROLYTIC PURIFICATION OF ALCOHOL.

M. Pontbriere, of the University of Lemberg, has published some interesting information with regard to the methods employed in France for purifying the products of the distillation of various substances containing sugar or starch, by means of the electrolytic process of M. Naudin. The alcohol of beetroot, for instance, when subjected to this treatment, and afterwards rectified in the usual manner, is entirely free from the unpleasant smell which characterises the crude product, whilst the alcohol of the Jerusalem artichoke, which is, as a rule, completely useless, yields as good results if treated by the Naudin process as that distilled from maize.

The earliest attempts in this direction were made by M. Esenmann, who, although he employed electricity, made no use of electrolysis. M. Esenmann passed a current of ozonised air at 70° C. through the liquid to be purified. To ozonise the air, it was sent through a glass tube placed between the terminals of an inductive coil. This process certainly oxidised some of the deleterious constituents of the liquid, but did not seem to act on the aldehydes which form the principal impurity of crude alcohol.

In the Naudin process the liquid is first hydrogenised by means of a Gladstone and Tribe zinc copper element. At M. Boulet's works, at Bapaume-lez-Rouen, wood or iron vats are used containing a number of zinc plates which are alternately flat and corrugated. The weight of zinc in a 150 hectolitre (3,300 gals.) vat is 800 kg. (0·8 tons); the number of plates is 116, and the active surface equals 1,800 square metres (19,380 square feet). Sulphate of copper is dissolved in the alcohol to be treated, and the reduced copper is deposited on the zinc plates. Five solutions containing 1 per cent. of copper sulphate are employed in succession. The total weight of copper deposited is 350 kg. (0·35 tons) in the case of the 150 hectolitre vat. The temperature at which the deposit is made is a matter of supreme importance; it ought to be from 30° C. to 35° C.; five degrees more or less injuriously affect the process. If the temperature is too low, the action ceases; if it is too high, the copper does not adhere firmly to the zinc plates. Each solution requires 24 hours to completely deposit the copper contained in it, so that the entire zinc copper process requires five days. Owing to the formation of oxidised zinc hydrate, 5 kg. of hydrochloric acid are added every week for every 150 hectolitres of alcohol treated.

The above process is generally sufficient to completely purify the crude alcohol, but owing to the presence of other impurities it is sometimes necessary to employ electrolysis before rectification. The voltameters in which this latter process takes place are glass cylinders 125mm. in diameter and 600mm. long, furnished with ebonite caps, through which pass the copper electrodes and the supply and overflow pipes. To treat 300 hectolitres in twenty-four hours M. Naudin employs twelve voltameters, two in series and six in parallel, using a total current of 30·15 amperes and an E.M.F. of 113·5 volts. The current is furnished by a four horse power Siemens shunt-wound dynamo. To neutralise the small quantity of hydrochloric acid employed to acidulate the solution some zinc is placed in the vat supplying the still in which the spirit is rectified.

M. Naudin has furnished the following figures as to the cost of each of the above operations in producing one hectolitre (twenty-two gallons) of pure alcohol.

Treatment of 300 hectolitres of products of the first distillation by the zinc-copper process in twenty-four hours.

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.SC.

(*Continued from page 726.*)

Dr Hertz's next Paper in order of publication in Wiedemann's *Annalen*, "On Some Induction Phenomena arising from Electrical Actions in Dielectrics" (Wiedemann's *Annalen*, Vol XXXIV., p. 273), contains an account of some researches undertaken with a view of obtaining direct experimental confirmation of the assumption involved in the most suggestive theory of electrical actions, viz., that of Faraday and Maxwell, that the well known electrostatic phenomena observed in dielectrics are accompanied by corresponding electrodynamic actions. The method of observation consisted in placing a secondary conductor adjusted to unison, as regards electrical oscillations, with the primary, as near as possible to the former, and in such a relative position that the sparks in the primary produced no sparking in the secondary. As the equilibrium could be disturbed and sparking induced in the secondary by the approach of conductors, it formed a kind of induction balance; but the point of special interest in connection with it was that a similar effect was produced when the conductors were replaced by insulators, provided the latter were of comparatively large size. The observed rapidity of the oscillations induced in the dielectrics showed

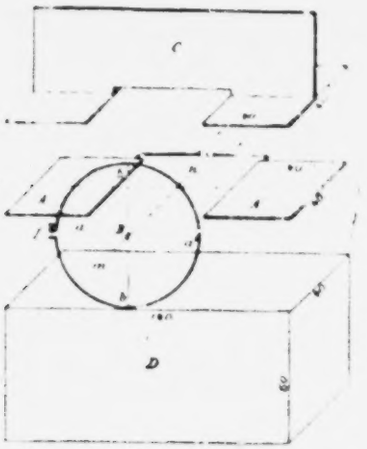

FIG. 10.

that the quantities of electricity in motion under the influence of dielectric polarisation were of the same order of magnitude as in the case of metallic conductors.

The apparatus employed is shown diagrammatically in Fig. 10, and was supported on a light wooden framework, not shown in the illustration. The primary conductor consisted of two brass plates, A A', with sides 40 centimetres in length, joined by a copper wire 70 centimetres long and half a centimetre in diameter, containing an air space of three quarters of a centimetre, with terminals formed of polished brass spheres. When placed in connection with a powerful induction coil, oscillations are set up, the period of which, determined by the dimensions of the primary, can be determined to within a hundred millionth of a second. The secondary conductor consisted of a circle, 35 centimetres in radius, of copper wire two millimetres in diameter, containing an air space, the length of which could be varied by means of a screw from a few hundredths of a millimetre, up to several millimetres. The dimensions stated were such as to bring the two conductors into unison, and secondary sparks up to six or seven millimetres in length could be obtained.

The circle was movable about an axis through its centre perpendicular to its plane, to enable the position of the air space to be varied. The axis was fixed in the position *m n* in the plane of A and A', and halfway between them. The centre of the circle was at a distance of 12 centimetres from the nearest points of A and A'.

When *f* was in either of the positions *a* or *a'* lying in the plane of A A' no sparking occurred in the secondary, while maximum sparking took place at *b* and *b'* 90° from the former positions. The E.M.F. giving rise to the secondary sparks is, as in previous experiments, partly electrostatic and partly electromagnetic, and the former being the greater will determine the sign of the resultant E.M.F. The oscillations must, for the reason previously explained, be considered as produced in the part of the secondary most remote from the air space. Assuming the E.M.F. and the amplitude of the resulting oscillation to be positive when *f* is in the position *b*, they will both be negative when *f* is at *b'*.

When the circle was slightly lowered in its own plane the sparking distance was increased at *b* and diminished at *b'*, and the null points lay at a certain distance below *a* and *a'*. The electrostatic E.M.F. is scarcely affected by such a displacement, but the integral of the E.M.F. of induction taken round the circle is no longer zero, and therefore gives rise to an oscillation which will be of positive sign whatever be the position of *f*, for the direction of the resultant E.M.F. of induction is opposite to that of the electrostatic E.M.F. in the upper half of the circle, and coincides with it in the lower half where the electrostatic E.M.F. has been assumed to be positive. Since the new oscillation so produced is in the same phase as the previously existing one their amplitudes must be added to give the resultant amplitude, which explains the phenomena.

Effects of the Approach of Conductors.—In making these observations it was found necessary to remove all conductors to a considerable distance from the apparatus, in order to obtain a complete disappearance of sparking at the points *a* and *a'*. Even the neighbourhood of the observer was sufficient to set up sparking when the air space *f* was in either of these positions, and the sparks had therefore to be observed from a distance. The conductors used for the experiments was of the form shown at C, Fig. 10, and consisted of thin metal foil. The objects kept in view in selecting the material and dimensions were to obtain a conductor which would give a moderately large effect, and having an oscillation period less than that of the primary.

When the conductor C was brought near to A A', it was found that the sparking distance decreased at *b* and increased at *b'*, and the null points were displaced upwards—that is, in the direction of C.

From the results of experiments already described it is evident that the effect of displacing A A' upwards would be the same, qualitatively, as that of a current in the same direction as that in A A directly above it. The effect produced by the approach of C was the reverse of this, and could be explained by an inductive action, supposing there were a current in C in the opposite direction to that in A A', which is exactly what must occur; for the electrostatic E.M.F. would give rise to such a current, and since the oscillations in C are more rapid than those of this E.M.F., the current must be in the same phase as the inducing E.M.F. The truth of this explanation was confirmed by the following experiments. The horizontal plates of the conductor C being left in the same position as before, the vertical plate was removed, and successively replaced by wires of increasing length and fineness, in order to lengthen the oscillation period of C. The effect of this was to displace the null points more and more in an upward direction, while at the same time they became less sharply defined, a minimum sparking taking the place of the previous absolute disappearance. The sparking distance at the highest point has previously been much less than at the lowest point, but after the disappearance of the null points it began to increase. At a certain stage the sparking distance at the two positions became equal, and then no definite minimum points could be found, but sparking took place freely at all positions of *f*. Beyond this stage the sparking distance at the lowest point diminished, and very soon two minimum points made their appearance close to it, not clearly defined at first, but gradually becoming more distinct, and at the same time

33576

approaching the points $a a'$, with which they ultimately coincided, when the minimum points again became absolute null points. These results are in agreement with the conclusion drawn from the former observations, for as the oscillation period of C approaches that of A A', the intensity of the current in the former increases, but a difference of phase arises between it and the exciting E.M.F. When the two are in unison the current in C attains its maximum, and, as in other cases of resonance, the difference of phase gives rise to a slightly damped oscillation, having a period of about a quarter that of the original one, which makes any interference between the oscillations excited in the circle B by A A' and C respectively impossible. These conditions clearly correspond to the stage at which the sparking distances at b and b' were equal. When the oscillation period of C becomes decidedly greater than that of A A', the amplitude of the oscillation in the former will again diminish, so that the difference in phase between it and the exciting E.M.F. will approach half of the original period. The current in C will therefore always be in the same direction as that in A A', so that interference between the two oscillations excited in B will again become possible, and the effect of C will then be opposite to its original effect. When the conductor C was made to approach A A' the sparks in B became much smaller, which is explained by the fact that its effect will be to increase the oscillation period of A A', and therefore to throw it out of unison with B.

Effects of the Approach of Dielectrics.—A very rough estimate shows that when a dielectric of large mass is brought near to the apparatus, the quantities of electricity set in motion by dielectric polarisation are at least as large as in metallic wires or thin rods. If, therefore, the action of the apparatus were unaffected by the approach of such masses it would show that, in contradiction to the theories of Faraday and Maxwell, no electro-dynamic actions are called into play by means of dielectric polarisation, or, as Maxwell calls it, electric displacement. The experiments, however, showed an effect similar to that which would be produced if the dielectric were replaced by a conductor with a very small oscillation period. In the first experiment made, the mass of dielectric consisted of a pile of books, 1·5 metre long, 0·5 metre broad, and 1 metre high, placed under the plates A A'. Its effect was to displace the null points through about 10° towards the pile. A block of asphalt (D, in Fig. 10), weighing 800 kilogrammes, and measuring 1·4 metre in length, 0·4 metre in breadth, and 0·6 metre in height, was then used in place of the books, the plates being allowed to rest upon it.

The following results were then obtained:—

(1.) The spark at the highest point of the circle was now decidedly stronger than that at the lowest point, which was nearer to the asphalt.

(2.) The null points were displaced through about 23° downwards—that is, in the direction of the block—and at the same time were transformed into mere points of minimum sparking, a complete disappearance being no longer obtainable.

(3.) When the plates A A' rested on the asphalt block the oscillation period of the primary was increased, as shown by the fact that the period of B had to be slightly increased in order to obtain the maximum sparking distance.

(4.) When the apparatus was moved gradually away from the block its action steadily diminished without changing its character.

(5.) The action of the block could be compensated by bringing the conductor C over the plates A A', while they rested on the block, the null points being brought back to a and a' when C was at a height of 11 centimetres above the plates. When the upper surface of the asphalt was 5 centimetres below the plates compensation was obtained when C was placed at a height of 17 centimetres above them, showing that the action of the dielectric was of the order of magnitude which had been anticipated.

The asphalte contained about 5 per cent. of aluminium and iron compounds, 40 per cent. of calcium compounds, and 17 per cent. of quartz sand. In order to make sure that the observed effects were not due to the conductivity of some of these substances, a number of further experiments were made.

In the first place the asphalte was replaced by a mass of the same dimensions of the so-called artificial pitch prepared from coal, and effects of a similar kind were observed, but slightly weaker, the greatest displacement of the null points amounting to 19°. Unfortunately this pitch contains free carbon, the amount of which it is difficult to determine, and this would have some conductivity.

The experiments were then repeated with a conductor, C, of half the linear dimensions of the former one, and smaller blocks of various substances, on account of the great cost of obtaining large blocks of pure materials. The substances used were asphalt, coal pitch, paper, wood, sandstone, sulphur, paraffin, and also a fluid dielectric, namely petroleum. With the smaller apparatus it was not possible to obtain quantitative results of the same accuracy as before, but the effects were of an exactly similar character, and left little room for doubt of the reality of the action of the dielectric.

The results might possibly be supposed to be due to a change in the distribution of the electrostatic E.M.F. in the neighbourhood of the dielectric, but in the first place Dr. Hertz states that he has been unable to explain the details of the observations on this hypothesis, and in the second place it is disproved by the following experiment.

The smaller apparatus was placed with the line $r s$ on the upper near corner of one of the large blocks, in which position the dielectric was bounded by the plane of the plates A A' and the perpendicular plane through $r s$, both of which are equipotential surfaces, so that if the action were electrostatic no effect should be produced by the dielectric. It was found, however, to produce the same effect as in other positions. It might also be supposed that the effects were due to a slight conductivity, but this could hardly be the case with such good insulators as sulphur and paraffin. Suppose, moreover, that the conductivity of the dielectric is sufficient to discharge the plate A in the ten thousandth of a second, but not much more rapidly. Then, during one oscillation, the plates would lose only the ten thousandth part of their charge, and the conduction current in the substance experimented on would not exceed the ten thousandth part of the primary current in A A', so that the effect would be quite insensible.

(To be continued.)

REVIEWS.

Traite Elementaire de l'Accumulateur Voltaique. By Fauré Kervigg. (Paris: Baudry and Co., 1888.)

Taken as a whole this book may be pronounced to be well worth the attention of all who are interested in the construction or the management of accumulators. The work is divided into four parts, dealing respectively with elementary principles, a description of various types of cells, technological data, and practical applications. In each section much useful matter is to be found, but in the author's desire to serve the *l'intérêt supérieur de la vérité* by discriminating between real inventions and mere adaptations, some curious omissions result. Of course, a book written by a Frenchman for Frenchmen is necessarily French; and it is no matter for surprise that the principal part is occupied with Gallic inventions. But, judging from the rate at which accumulators are being made both in England and Belgium, it seems strange that only a few pages should be given to the "foreign" manufacturer. We are disposed to attribute this to the patriotism of the author.

Chapter IV. contains sketches of some plates perhaps not generally known in England to the ordinary electrician, though most of them have been tried in approximately the same form by more than one manufacturer in this country. The Faure-Sellon Volckmar type is briefly discussed, and some comparative tables are given, showing weights, outputs, &c., for lighting and traction cells. The use of oxygenated water with the electrolyte, according to the author, gives an increased rate of discharge, a higher voltage, and a greater capacity. Non-oxidisable sulphates are also mentioned as possessing the same virtue. But, unfortunately, we are told that this increase of activity results in damage to the plate, as ordinarily made.

141·6	95·6 ,,

The trials Nos. 13, 14, and 15 were taken without condenser, and with non-inductive resistances in its place. In trial No. 13 this resistance was a length of fine platinum wire (hot). In trial Nos. 14 and 15 the resistance was a 96 volt 10 candle power Edison lamp, offering 230 ohms resistance at equivalent illumination. In calculating the current strengths for these three observations, the resistance of the voltameter itself was required. It was measured in two ways—1st, by means of the quadrant electrometer, and the potential differences it indicated on the known resistance, and on the voltameter; 2nd, by rapidly substituting a non inductive resistance alternately with the voltameter in the lamp circuit, and adjusting this resistance until the illumination was equal in both cases. These two methods concurred in showing the resistance of the voltameter to be 30 ohms, and the maximum resistance it offered through the whole series was 35 ohms.

The table shows that

When the current density per square centimetre of either electrode was—	The per cent. of calculated gas actually liberated was—
20·0	52
59·3	96·3

These results, corroborated by several previous series, go to show that for a rate of alternation of 200 per second, and currents of between 0·1 and 0·35 amperes, the quantity of gas generated by an alternating current in a voltameter is approximately equal to that generated by an equal continuous current when the mean current density at the surface of the electrode is above 50 amperes per square centimetre of each; that below that density the quantity of gas developed rapidly diminishes, and that below one ampere per square centimetre soon disappears.

Also that the resistance of a voltameter with very small plates, traversed by an alternating current, is much less than that it would offer to an equal continuous current. Were this not the case, the resistance of a voltameter for alternating current measurements might for many purposes prove prohibitively great.

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.Sc.

(Continued from page 696.)

Other Positions of the Secondary Circuit.—Dr. Hertz made numerous observations with the secondary circuit in other positions, but in no case were any phenomena observed which were not completely in accordance with theory. As an example of these consider the following experiment.

The secondary was first placed in the horizontal plane in the position V. (Fig. 8*), and the air space was in the position relatively to the primary. The circle was then turned about a horizontal axis through its centre and parallel to the primary, so as to raise the air space above the horizontal plane. During this rotation θ remained equal to 90°, and the value of β remained nearly constant, but α varied approximately in the same ratio as $\cos \Psi$, Ψ being the angle between the plane of the circle and the horizontal, for α is proportional to the number of magnetic lines of force passing through the circle. Let α_0 be the value of α in the initial position, then in the other positions its value would be $\alpha_0 \cos \Psi$, and therefore the sparking distance should be given by the expression $\alpha_0 \cos \Psi + \beta$, in which α_0 was known to be greater than β. This was confirmed by observation, for it was found that as the air space increased its height above the horizontal plane the sparking distance diminished from 6 millimetres down to 2 millimetres, its value when the air space was at its greatest distance above the horizontal plane. During the rotation through the next quadrant the sparking distance diminished almost to zero, and then increased to the smaller maximum of 2·5 millimetres, which it attained when the circle had turned though 180°, and was therefore again horizontal. Similar results were obtained in the opposite order, as the circle was rotated from 180° to 360°. When the circle was kept with the air space at its maximum

* See *The Electrician*, October 5th, 1888, page 697.

height above the horizontal plane, and then raised or lowered bodily without rotation, the sparking distance was found to diminish in the former case and to increase in the latter, results completely in accordance with theory.

Forces at Greater Distances.—Experiments with the secondary at greater distances from the primary are of great importance, as the distribution of E.M.F. in the field of an open circuit is very different according to different theories of electrodynamic action, and the results may, therefore, serve to eliminate some of them as untenable. In making these experiments, however, an unexpected difficulty was encountered, as it was found that at distances of from 1 to 1·5 metres from the primary the maximum and minimum, except in certain positions, became indistinctly defined; but when the distance was increased to upwards of two metres, though the sparks were then very small, the maximum and minimum were found to be very sharply marked when the sparks were observed in the dark. The positions of maximum and minimum were found to occur with the circle in planes at right angles to each other. At considerable distances the sparking diminished very slowly as the distance was increased. Dr. Hertz was not able to determine an upper limit to the distance at which sensible effects took place, but in a room 14 metres by 12, sparks were distinctly observed when the primary was placed in one corner of the room, wherever the secondary was placed. When, however, the primary was slightly displaced, no effects could be observed, even when the secondary was brought considerably nearer. The interposition of solid screens between the two circuits greatly diminished the effect.

Dr. Hertz mapped-out the distribution of force throughout the room by means of chalk lines on the floor, putting stars at the points where the direction of the E.M.F. became indeterminate. A portion of the diagram obtained in this manner is

FIG. 9.

shown on a reduced scale in Fig. 9, with respect to which the following points are noteworthy:—

1. At distances beyond three metres the E.M.F. is everywhere parallel to the primary oscillation. Within this region, therefore, the electrostatic E.M.F. is negligible in comparison with the E.M.F. of induction. Now, all the theories of the mutual action of current elements agree in giving an E.M.F. of induction inversely proportional to the distance, while the electrostatic E.M.F., being due to the differential action of the two extremities of the primary, is approximately inversely proportional to the cube of the distance. Some of these theories, however, are not in accordance with the experimental result, that the effect diminishes much more rapidly in the direction of the primary oscillation than in a direction at right angles to it, induced sparks being observed at a distances exceeding 12 metres in the latter direction, while they disappeared at a distance of about four metres in the former direction.

2. That, as already proved, for distances less than one metre the distribution of E.M.F. is practically that of the electrostatic E.M.F.

3. There are two straight lines, at all points of which the direction of the E.M.F. is determinate, namely, the line in which the primary oscillation takes place, and the perpendicular to the primary through its middle point. Along the latter the E.M.F. does not vanish at any point, the sparking diminishes gradually as the distance is increased. This, again, is inconsistent with some of the theories of mutual action of current elements, according to which it should vanish at a certain definite distance. A very important result of the investigation is the demonstration of the existence of regions within which the direction of the E.M.F. becomes indeterminate. These regions form two rings encircling the primary circuit. Since the E.M.F. within them acts very nearly equally in every direction, it must assume different directions in succession, for, of course, it cannot act in different directions simultaneously.

The observations, therefore, lead to the conclusion that within these regions the magnitude of the E.M.F. remains very nearly constant, while its direction varies through all the points of the compass at each oscillation. Dr. Hertz states that he has been unable to explain this result, as also the existence of overtones, by means of the simplified theory in which the higher terms of the expansion of F are neglected, and he considers that no theory of simple action at a distance is capable of explaining it. If, however, the electrostatic E.M.F. and the E.M.F. of induction are propagated through space with unequal velocities, it admits of very simple explanation. For within these annular regions the two E.M.F.'s are at right angles and of the same order of magnitude; they will therefore, in consequence of the distance traversed, differ in phase, and the direction of the resultant will turn through all the points of the compass at each oscillation.

This phenomenon appears to him to be the first indication which has been observed of a finite rate of propagation through space of electrical actions, for if there is a difference in the rate of propagation of the electrostatic and electrodynamic E.M.F., one at least of them must be finite.

At the end of the Paper in which the preceding experiments are described Dr. Hertz describes some observations which he has made on the conditions at the primary sparking point which affect the production of sparks in the secondary circuit. He finds that illuminating the primary spark diminishes its power of exciting rapid oscillations, the sparks in the secondary being observed to cease when a piece of magnesium wire was burnt, or an arc lamp lighted, near the primary sparking point. The observed effect on the primary sparks is that they are no longer accompanied by a sharp crackling sound as before. The effect of a second discharge is especially noteworthy, and it was found that the secondary sparks could be made to disappear by bringing an insulated conductor close to the opposed surfaces of the spheres forming the terminals at the primary air space, even when no visible sparking took place between the latter and the insulated conductor. The secondary sparking could also be stopped by placing a fine point close to the primary air space, or by touching one of the opposed surfaces of the terminals with a piece of sealing-wax, glass, or mica. Dr. Hertz states that further experiments have led him to conclude that, even in these cases, the effect is due to light too feeble to be perceived by the eye, arising from a side discharge. He points out that these effects afford another example of the effects of light on electric discharges, which have been observed by E. Wiedemann, H. Ebert, and W. Hallwachs.

(To be continued.)

ALUMINIUM AND ALUMINIUM ALLOYS.*

The Swiss Metallurgical Society in Lauffen-Neuhausen, Canton Schaffhausen, has succeeded in producing aluminium alloys in large quantities by means of Héroult's method. In this method the electric current is employed for fusing refractory earths containing aluminium. The negative electrode is composed of the metal, copper, iron, or tin, with which it is desired to alloy the aluminium; the positive electrode is composed of a group of carbons dipping into the molten argillaceous earth. The current is generated at these works by means of a vertical 300 horse-power Jonval turbine (Fig. 1) driving two dynamos of 6,000 amperes and 20 volts each, which are excited by a smaller Erreger

* Abstracted from the *Schweizerische Bauzeitung*, 4th August 1888.

fundamental vibration of the secondary, since it is symmetrical on opposite sides of the air space.

The term $B \cos \frac{2\pi s}{S}$ will give a force acting in the same direction in the two quadrants opposed to the air space, and will excite the fundamental vibration. In the two quadrants adjacent to the air space it will give a force in the opposite direction, but its effect will be less than that of the former one. For the current is zero at the extremities of the circuit, and therefore the electricity cannot move so freely as near the centre. This corresponds to the fact that if a string fastened at each end has its central portion and ends acted on respectively by oppositely directed forces, its motion will be that due to the force at the central portion, which will excite the fundamental vibration if its oscillations are in unison with the latter. The intensity of the vibration will be proportional to B. Let E be the total E.M.F. in the uniform field of the secondary, ϕ the angle between its direction and the plane of the latter, and θ the angle which its projection on this plane makes with the radius drawn to the air space. Then we shall have approximately

$$E = E \cos \phi \sin \left(\frac{2\pi}{S} s + \theta \right),$$

and therefore, $B = E \cos \phi \sin \theta$.

B therefore, is a function simply of the total E.M.F. due both to the electrostatic and electrodynamic actions. It will vanish when $\phi = 90$ —that is to say, when the total E.M.F. is perpendicular to the plane of the circle, whatever be the position of the air space on the circle. B will also vanish when $\theta = 0$—that is to say, when the projection of the E.M.F. on the plane of the circle coincides with the radius through the air space. If the position of the air space on the circle is varied, the angle θ will vary, and, therefore, also the intensity of the vibration and the sparking distance. The sparking distance corresponding to the second term of the expansion for E can, therefore, be represented approximately by a formula of the form $\beta \sin \theta$.

Now the oscillations giving rise to sparks of lengths α and $\beta \sin \theta$ respectively are in the same phase. The resulting oscillations will therefore be in the same phase, and their amplitudes must be added together. The sparking distance being approximately proportional to the maximum total amplitude may therefore also be obtained by adding the sparking distances due to the two oscillations respectively. The sparking distance will therefore be given as a function of the position of the air space on the secondary circuit by the expression $\alpha + \beta \sin \theta$. Since the direction of the oscillation in the air space does not come into consideration we are concerned only with the absolute value of this expression, and not with its sign. The determination of the absolute values of the quantities α and β would involve elaborate theoretical investigations, and is, moreover, unnecessary for the explanation of the experimental results.

Experiments with the Secondary Circuit in a Vertical Plane.—When the circle forming the secondary circuit was placed with its plane vertical, anywhere in the neighbourhood of the primary, the following results were obtained:—

The sparks disappeared for two positions of the air space, separated by 180°, namely, those in which it lay in the horizontal plane through the primary, but in every other position sparks of greater or less length were observed.

From this it followed that the value of α must have been constantly zero, and that θ was zero when the air space was in the horizontal plane through the primary.

The electromagnetic lines of force must therefore have been perpendicular to this horizontal plane, and therefore consisted of circles with their centres on the primary, while the electrostatic lines of force must have been entirely in the horizontal plane, and therefore this system of lines of force consisted of curves lying in planes passing through the primary. Both of these results are in agreement with theory.

When the air space was at its greatest distance from the plane the sparking distance attained a maximum value of from 2 to 3 millimetres. The sparks were shown to be due to the fundamental vibration, by slightly varying the secondary, so as to throw it out of unison with the primary, when the sparking distance was diminished, which would not have been the case if the sparks had been due to overtones. Moreover, the sparks disappeared when the secondary was cut at its points of intersection with the horizontal plane through the primary, though these would be nodal points for the first overtone.

When the air space was kept at its greatest possible distance from the horizontal plane through the primary, and turned about a vertical axis, the sparking distance attained two maxima at the points for which $\phi = 0$, and almost disappeared at the points for which $\phi = 90$.

The lower half of Fig. 8 shows the different positions of minimum sparking. A A is the primary conductor, and the lines $a\ a$ represent the projections of the secondary circuit on the horizontal plane. The arrows perpendicular to these give the direction of the resultant lines of force. As this did not anywhere vanish in passing from the sphere A to the sphere A, it could not change its sign.

The diagram brings out the two following points:—

(1) The distribution of the resultant E.M.F. in the vicinity of the rectilinear vibration is very similar to that of the electrostatic E.M.F. due to the action of its two extremities. It should be specially noted that near the centre of the primary the direction is that of the electrostatic E.M.F., showing that it is more powerful than the electrodynamic, as required by theory.

(2) The lines of force deviate more rapidly from the line A A than the electrostatic lines, though this is not so evident

Fig. 8.

on the reduced scale of the diagram as in the author's original drawings on a much larger scale.

It is due to the components of the electrostatic E.M.F. parallel to A A being weakened by the E.M.F. of induction, while the perpendicular components remain unaffected.

Experiments with the Secondary Circuit in a Horizontal Plane.—The results obtained when the plane of the secondary was horizontal can best be explained by reference to the upper half of the diagram in Fig. 8.

In the position I., with the centre of the circle in the line A A' produced, the sparks disappeared when the air space occupied either of the positions A_1 or A_2, while two equal maxima of the sparking distance were obtained at a_1 and a_2, the length of the spark in these positions being 2·5 millimetres. Both these results are in accordance with theory.

In the position II. the circle is cut by the electromagnetic lines of force, and, therefore, α does not vanish. It will, however, be small, and we should expect that the expression $\alpha + \beta \sin \theta$ would have two unequal maxima $\beta + \alpha$ and $\beta - \alpha$, both for $\theta = 90°$, and having the line joining them perpendicular to the resultant E.M.F., and between these two maxima we should expect two points of no sparking near to the smaller maximum. This was confirmed by the observations.

The maximum sparking distances were 3·5 millimetres at a_2 and 2 millimetres at a'_2. Now with the air space at a_2 the sphere A being positive, the resultant E.M.F. in the opposite portion of the circle will repel positive electricity from A, and therefore tend to make it flow round the circle clockwise. Between the two spheres the electrostatic E.M.F. acts from A

towards A, and the opposite E.M.F. of induction in the neighbourhood of the primary acts from A to A, parallel to the former, and acting more strongly on the nearer than on the farther portion of the secondary, tends to cause a current in the same direction as that due to the former, namely, in a clockwise direction. Thus the resultant E.M.F. is the sum of the two as required by theory, and in the same way it is easily seen that when the air space is at a'_2 the resultant E.M.F. is equal to their difference.

As the position III. is gradually approached, the maximum disappears, and the single maximum sparking distance a was found to be 4 millimetres in length, having opposite to it a point of disappearance a_1. In this case clearly $a = \beta$, and the sparking distance is given by the expression $a(1 + \sin\theta)$. The line $a_1 a$ is again perpendicular to the resultant E.M.F.

As the circle approaches further towards the centre of A A, α will become greater than β, and the expression $\alpha + \beta \sin\theta$ will not vanish for any value of θ, but will have a maximum $\alpha + \beta$ and a minimum $\alpha - \beta$, and in the experiments it was found that the sparks never entirely disappeared, but varied between a maximum and a minimum, as indicated by theory.

In the position IV. a maximum sparking distance of 5·5 millimetres was observed at a_4 and a minimum of 1·5 millimetre at a'_4.

In the position V. there was a maximum sparking distance of 6 millimetres at a_5 and a minimum of 2·5 millimetres at a'_5. In these experiments the air space should be screened off from the primary in the latter positions as well as in the earlier ones, in which it is unavoidable, as otherwise the results would not be comparable.

In passing from the position III. to the position V. the line $a_1 a$ rapidly turned from its position of parallelism to the primary circuit into a position perpendicular to it. In the latter positions the sparking was essentially due to the inductive action, and therefore the author was justified, in the experiments described in my previous Papers, in assuming the effect in these positions to be due to induction.

Even in these positions, however, the sparking is not totally independent of electrostatic action, except when the air space is half way between the maximum and minimum positions, and therefore $\sin\theta = 0$.

(To be continued.)

THE USE OF ELECTRIC MOTORS ON SHIPBOARD.*

The use of electric motors is extending very rapidly ashore, and naturally raises the question whether there is a field for them on shipboard. The transmission of energy by electricity possesses many points of advantage over any other system in being more economical when energy is to be transmitted to a distance, or when it has to be subdivided into a number of parts. The former has no application on shipboard, where distances are short, but the latter becomes almost essential for the modern navy.

A good dynamo will give 90 per cent. of the mechanical energy it receives in the form of available electrical energy in its external circuits. If a good motor is placed in this circuit 90 per cent. of this electrical energy, or about 81 per cent. of the work of the engine, can be obtained as mechanical work. The loss in transmission is 20 per cent., and the cost of dynamo and motor renders such a system inadmissible in comparison with the simple one of placing a steam engine where the work is to be done. If, however, the power is required in twenty places instead of in one, the question becomes materially different, and this is the one inviting our attention.

In the new cruisers one of the first impressions received is that of complexity and confusion arising from the number of small engines scattered over the vessels. Nor is the feeling dispelled by a closer examination, for the ship is found to be a labyrinth of steam, exhaust, and circulating pipes, complex in arrangement, and requiring constant care and attention to keep in order. Joints and valves leak, steam condenses, and water freezes, totally disabling some part of the mechanism. If injuries occur, repairs are difficult and frequently impossible with the ships resources, and an important engine may be disabled for months, or until the arrival of the vessel in port. A still more important objection to this complicated system of steam circulation in men of war is found in its liability to injury in action, and the danger to the crew which such injury might bring about. A single pipe cut by shot might disable a very important part of the ship's offensive apparatus, and pipes so injured are difficult to repair, and require time which could not be spared. The escape of steam in such a case would inevitably interfere with the fighting of the ship, and might cause loss of life or even a panic in the crew. If, therefore, it is necessary to use so many auxiliary motors, is steam the best vehicle for the transmission of power?

The electric motor is for equal power smaller than also is the steam engine, is more efficient, involves less waste in transmission, and has small mains, which are therefore less liable to injury, and admit of rapid repair of injuries. With the low potential used on shipboard there is, moreover, no danger to the persons, and a broken main could be stopped without the delay of turning off the current. Every objection against the indiscriminate use of steam engines is removed by the use of the electric motor. A motor is moreover, portable, and power may thus be quickly obtained in any place in the ship where the motor may be fastened down.

On grounds of utility, therefore, the motor appears to possess decided advantages. These appear to exist equally in economy. Small engines are notoriously uneconomical as compared with large ones. Small motors and dynamos are less so. By concentrating the whole auxiliary power of the ship in the dynamo room large economical compound condensing engines may be used in driving high efficiency dynamos, and the power thus obtained distributed through large mains to the motors with very slight loss. The question of economy therefore rests upon the amount of subdivision, and is apparently in favour of the electric motor under just the circumstances in which distribution by steam becomes complex, and the loss due to using a number of uneconomical engines forms a large total aggregate. The question of economy of coal is one of the most important to be faced, and becomes paramount in a ship, which, without plenty of coal in her bunkers, is a mere helpless steel box, drifting at sea. Is it not advisable to seriously consider the saving and general advantages to be obtained by the high economy of large engines of the best type, and the high efficiency of well-designed dynamos and motors, in place of the notorious wastefulness, heat, dirt, and noise of small auxiliary engines?

In order to carry out such a plan it is only necessary to connect the motors to the incandescent light mains. It will be necessary to closely analyse the demands for power, and to place in the dynamo room a sufficient number of dynamos to supply the maximum required to be used at any time. The paramount consideration should be to have a reserve in action, and it is probable that more power will be needed then, through the use of gun carriages and other motors and search lights, than will be saved by the diminished use of incandescent lights. The dynamo room in this case becomes a central station for light and power, and valuable information may be derived from the experience of central stations ashore. It seems to be settled now in ordinary practice that, in cases where the load varies largely, it is in the long run most economical to use several engines of medium size, throwing in one after the other as the demand increases, rather than to employ one or two large engines which must generally be operated at partial load.

The objection to such a system is, that although the danger of action is not diffused over the whole ship it is concentrated in one place, and any injury there would cripple the ship. This is merely placing the dynamos in the same category as the engines and boilers, and, like them, the dynamos room must have all protection that can be given it. It should always be below the protective deck, when there is one, and in other cases below the water line. The mains should consist of several parts in parallel connected together by copper wire spans at intervals. Each main becomes then a net work of conductors, and although this entails greater first cost, it reduces loss in transmission to a negligible quantity, and guarantees safety and durability. The distribution should be made as much as possible below the protective deck, branch mains being generally vertical. Every circuit necessary in action should be thoroughly accessible for repairs, while at the same time receiving all possible protection. The highest insulation is of course demanded.

The simplicity of such a system is in marked contrast with that of steam distribution. All incandescent lights, search lights, motors are connected in parallel, and any one may be put into or out of action by the movement of a single switch.

Apart from all advantages of distribution, the electric motor is the most efficient, compact, noiseless and simple vehicle for the transmission of energy that is known. If well made, it requires only ordinary care and attention to be always ready for use. Its principal danger on shipboard is from salt water, but with proper care this is small.

Nothing like a complete presentation of so wide a subject can be given within the limits of a single article, but the foregoing may call attention to some of the necessities of our service, and also to some fields in which experimental work may well be carried on.

* Extract from an official report to the United States Government.

of a flash being enormous, a very high difference of potential exists between every point of the conductor and the earth, however well the two are connected; hence the neighbourhood of a lightning conductor is always dangerous during a storm, and great circumspection must be exercised as to what metallic substances are wittingly or unwittingly brought near or into contact with it. When a building is struck the oscillations are energetic all through its neighbourhood are so violent that every piece of metal is liable to give off sparks, and gas may be ignited even in neighbouring houses. If one end of a rain water gutter is attached to a struck lightning conductor the other end is almost certain to spit off a long spark, unless it is also metallically connected. Electric charges splash about a metallic mass of metal, as does the sea during an earthquake when a mountain top drops into it.* Even a small space near combustible substances is to be dreaded.

The electrical disturbance is conveyed to a conductor through the ether or space surrounding it, and so the more surface it exposes the better. Better than a single rod or tape is a number of separate lengths of wire, each thick enough not to be easily melted, and well separated so as not to interfere with each other by mutual induction.

The liability of rods to be melted by a flash can be easily overestimated. A rod usually fails by reason of its inertia or obstruction, and consequent inability to carry off the charge without spittings and side flashes; it very seldom fails by reason of being melted. In cases where a thin wire has got melted, the energy has been largely dissipated in the effort, and it has acted as an efficient protector, though, of course, for that time only. Large sectional area offers very little advantage over moderately small sectional area, such as No. 8 B.W.G.

Points, if numerous enough, serve a very useful purpose in neutralising the charge of a thunder cloud hovering over them, and thus often prevent a flash; but there are occasions when, if not mitigated in the laboratory, when they are of no avail. For instance, when one upper cloud sparks into a lower one, which then suddenly overflows to earth. In the case of these sudden rushes, there is no time for a path to be prepared by points, no time for points to exert any protective influence, and points then get struck by a violent flash just as if they were knobs. Discharges of this kind are the only ones likely to occur during a violent shower, because all leisurely effects would be neutralised by the raindrops better than by an infinitude of points.
